distance. Figure 7 shows a real tachograph trace, Table 1 shows the tabulated analysis, and Figure 8 shows the resulting plot. (This trace and analysis is used for the case example at the end of this article.)

There are various approaches to making these measurements. Taking the speed from the chart is relatively straightforward and can be done from a photographic enlargement or with a traveling microscope. Allowance has to be made for the accuracy of the speed recordings. Measurement of the time intervals is, however, not at all easy. Because the chart rotates just once in 24 h, 1 min occupies only 0.25° , and in 1 s it turns through only 15 s of arc. It is usual to mount the chart beneath a microscope on a rotating table that is turned by a micrometer.

Figure 8 Plot of speed data from Figure 7 against distance.

Figure 9 The Kienzle microscope with computer-linking modifications.

Figure 9 shows one such microscope, as produced by VDO Kienzle. A glass plate etched with a vertical cursor line, $3 \mu\text{m}$ wide, lies over the chart, and this combines with a horizontal line in one eyepiece to form a 'crosswire' in the field of view. Points for measurement are brought successively under the crosswire by rotating the chart table and moving it backward and forward, and transducers are attached to these two movements. Signals from the transducers, which are interpreted as time and speed, are fed to a microcomputer, where listings of these quantities and graphs of speed versus time and distance are produced.

It is very important to recognize, when measuring time intervals, that the line along which the recording stylus moved was unlikely to have passed exactly either through the center of rotation of the chart when mounted on the microscope or when mounted in the tachograph instrument, or through the geometric center of the chart itself. This is illustrated in an exaggerated form in Figure 10. If the vertical cursor is not arranged such that it lies along the line on which the stylus moved, any time intervals measured between points at different speeds will be in error. In the VDO Kienzle microscope, the glass plate carrying the cursor line can be swiveled about a point at the outer edge of the chart, and this adjustment is used to set the line in what the analyst judges to be the correct position.

Figure 10 The need for an adjustable cursor when analyzing a chart.

The Accuracy of the Speed Record

The EEC Regulations require that having been installed and calibrated, the analog tachograph record may not have an error in its speed figures greater than $\pm 6 \text{ km h}^{-1}$. The analyst may be content to use this as a probable error figure, but the author's experience is that although the error is generally not greater than $\pm 3 \text{ km h}^{-1}$, there are occasional cases where it is substantially more than $\pm 6 \text{ km h}^{-1}$. It is therefore desirable that the calibration in each case be checked, and various methods have been devised for this.

Calibration Checks on the Tachograph Installation

The most straightforward method of checking the accuracy of a tachograph system is to employ a 'rolling road' of the sort used when tachographs are installed in vehicles. A chart is placed on the instrument, and the vehicle is then effectively driven through a range of known speeds. The chart will then show how each speed is recorded, from which the amount of error is found.

Some agencies find the rolling road method quite inconvenient, and instead use a method that requires no special facilities and that can be employed in any open space.

The procedure is in two stages: first, the signal sent from the vehicle's gearbox is measured (either as pulses per kilometer in electronic systems or turns per kilometer in mechanical ones) in one of two ways, and the second, the way the tachograph instrument responds to a known set of input signals is found.

The first of the two ways of measuring the signal is called the 20-m track and is one that may actually be used by some installers. It is fully described in manuals produced by tachograph manufacturers for the guidance of their agents. It is appropriate for vehicles that can be moved slowly in a straight line; thus, they need not be fully mobile, and may have, for example, accident damage to the steering gear or the engine coolant system. The test can even be performed by towing the vehicle.

In this method, the drive to the tachograph is either disconnected and a turn or pulse counter is attached to it, or, with later electronic models, a pulse counter is plugged into a socket in the head itself. The vehicle itself is then driven slowly on a straight and level surface for 20 m, the distance being measured exactly. From the number of pulses and the distance, the rate per meter is calculated: this is usually referred to as the w figure.

The second way is called the static method and is appropriate for vehicles that cannot be moved, either through accident damage or through restriction of space. In this method, a turn or pulse counter is attached in the same way as in the 20-m track method. One of the driven wheels of the vehicle is then lifted off the ground, and its circumference is measured with a tape; later, the other driven wheels are also measured. The raised wheel is then rotated manually ten times and the resulting turn or pulse reading is noted. From these data, the w figure can be calculated, remembering to take account of the effect of the axle differential, which averages the rotation of the wheels at each end: thus, with one wheel being stationary and the other wheel being turned, ten turns of the single wheel is equivalent to five turns of the two wheels together and therefore of the whole axle.

If the accident damage is so great that neither of these methods can be used, then the investigator may have to resort to examining gear trains and counting gear teeth.

Having determined w , the response of the tachograph instrument itself is found by driving it in steps through its speed range with a sequence of signals generated by a specially constructed test unit. These units are produced by the tachograph manufacturers for the use of their installation agents, and display either the mechanical rotation rate or the electronic pulse rate (in units of min^{-1}). A new tachograph chart is put in the instrument, and a test chart similar to that in [Figure 11](#) is produced.

The sequence of tests in [Figure 11](#) is given as follows:

1. The instrument is taken up to its maximum speed (140 km h^{-1} in this example) and then very quickly back to zero to check the straightness of the recording stylus movement.
2. This is repeated three times.
3. Next, the instrument is taken to an indicated speed of 60 km h^{-1} : at this speed the input figure (in min^{-1}) is known as the characteristic coefficient or k figure, and

Figure 11 A typical head test chart.

should be, in a correctly calibrated system, approximately equal to the w figure of the vehicle.

4. The speed is taken from zero up to the maximum in 20 km h^{-1} steps, holding each step for 2 min, and then back down to zero at the same speed between the steps (130 km h^{-1} , 110 km h^{-1} , etc.).
5. Finally, the instrument is run at 60 km h^{-1} for as long as it takes 1 km to be recorded on its odometer, and the actual number of turns or pulses delivered is noted: this should equal the κ figure. During the last test, the activity mode switch is also changed through its four settings.

The information from part (4) of the test can now be used, together with the w figure, to construct a graph of how the recording on the chart at any point relates to the true speed. This can be done manually or by using the software associated with the Kienzle computer-linked microscope.

The 'Route-Trace' Method of Calibration

An alternative to the direct methods of calibration is the so-called route-trace method. This can only be used when the route the vehicle has taken is known and is particularly appropriate when the vehicle is unavailable for testing or has been so seriously damaged as to make the other methods impossible. The tachograph record can also be used to find the route that a vehicle has taken (see [Route Tracing](#) below). The calibration

method is an inversion of this procedure and briefly involves attempting to match the recorded pattern of driving to the known route. A system that is in calibration will give an immediate match, whereas one that is out of calibration will require an adjustment of its speed by some factor before the match is found. Thus, the calibration method is one of finding what this adjustment factor is.

Problems of Interpretation

Once the cursor on the analyzing microscope has been correctly aligned and the errors, if any, in the speed record have been determined, the chart can be analyzed. However, the limitations of the recording and the individual instruments must be recognized.

Time Intervals

The clock in most tachograph instruments advances the chart in 1-s step, and it is, therefore, not possible in principle to measure the time at a particular point on the chart with a precision greater than $\pm 1 \text{ s}$. When measuring the interval between two points, the precision can therefore never be greater than $\pm 2 \text{ s}$. In any case, the edge of the speed recording trace is insufficiently smooth for these steps to be resolved. With a good trace, a confidence of $\pm 2 \text{ s}$ can probably be assumed, but in some instruments an unsteadiness will be evident, which means that wider uncertainty must be accepted. It is found that although some manufacturers' instruments yield consistently good traces, other manufacturers produce tachographs that are invariably poor.

Figure 12 shows an example of a poor trace. The drive train from the clock to the chart is somewhat loose, and allowing a generally unsteady speed trace as the stylus moves up and down, it permits the stylus, as it falls after rising to a maximum, to track back along the groove it has made on the chart instead of drawing a new line. This effectively drives the clock backward for a few seconds (20 s being typical) until the slack is taken up, and only then the stylus will start to follow a new track.

In some tachographs, severe steering or swerving may cause the recording trace to deviate, and a likely example appears in **Figure 13**, where the period of perfectly constant speed, which can be seen just before the final descent of the trace to zero speed, was probably caused by a swerving action that made to chart shift slightly within the instrument.

Impacts to the Vehicle

A severe impact to the vehicle will generally produce a disturbance of the tachograph recording traces (**Figures 7 and 13**). When such a disturbance is apparent on the speed trace, it is obviously an indication of the speed of the vehicle at the moment of impact and is an item of the information easily read from the chart. However, some caution is needed before interpreting it. The disturbance was properly caused by a shock to the tachograph itself, and its magnitude therefore depends on the proximity of the impact to the instrument. A collision with a pedestrian, where the pedestrian meets the vehicle very close to the instrument panel, can cause a clear disturbance,

Figure 12 An unsteady trace from a Jaeger mechanical instrument.

whereas a severe impact from another vehicle to the rear of an articulated lorry may have little or no effect on the recording.

If heavy braking is taking place at the time of the impact, the speed at which the disturbance appears may be affected by other factors.

Finally, a severe impact will often derange the instrument for at least a few seconds, such that little or no reliance can be placed on any features that may immediately follow it.

Response of the Instrument

The EEC Regulations require tachograph instruments to be able to follow 'acceleration changes' of 2 m s^{-2} . Since during braking the deceleration of a vehicle may well be as much as 7 m s^{-2} , there is the possibility that the speed-recording stylus may not be able to keep up with the changing speed. This does not, in fact, appear to be a problem in Kienzle, Motometer, Jaeger, and mechanical Veeder Root tachographs, but there is a difficulty with older electronic Veeder Root instruments.

Earlier Veeder Root 1200 and 1400 series tachographs only just met the 2 m s^{-2} requirement; early 8300 series models had a response of 2.5 m s^{-2} , whereas later 8300 series and all 8400 series models have a response of 5.7 m s^{-2} . The consequence of a response of 2 or 2.5 m s^{-2} is that during heavy braking, the speed being recorded at any moment will be greater than the true speed, and any event recorded during the braking,

Figure 13 Chart showing lock-up followed by impact at zero speed.

for example an impact, will be shown at too high a speed. It also means that it is not possible for an analyst to give an opinion as to whether a particular piece of braking was at a normal or an emergency rate.

A response of 5.7 m s^{-2} , however, is much closer to the braking rate, which can be expected of a lorry in an emergency, and will generally allow a reasonable speed for an impact to be recorded.

An even higher response rate leads to a difficulty where there has been a wheel slip during braking.

Tire Slip Effects

The tachograph records the speed of rotation of the wheels to which it is connected, almost always the driven wheels of the vehicle. Therefore, if for some reason those wheels slip, that is, rotate at a speed that does not correspond to the speed of the vehicle over the ground, then the recording will be in error.

Wheel slip particularly occurs during heavy braking, notably when the driven wheels lock. An instrument with a fast response will react to wheel locking as though the vehicle had instantaneously come to a halt: the stylus will fall very quickly to its base position even though the vehicle is still traveling forward, and an impact may even appear to have been at zero speed. An example is shown in [Figure 13](#), where, because the vehicle has skidded, the prominent impact feature will certainly be at a level much lower than the true speed. The operation of

an antilock braking system will also cause the speed of the wheels to be less than the road speed of the vehicle.

The opposite can occur if one of the driven wheels lifts off the road, allowing it to spin. This typically occurs as a vehicle starts to roll onto its side. In [Figure 14](#), the speed at C would appear to be that at which the accident has occurred. In fact, the correct speed is at B, from which the trace has jumped to C, as the wheels on one side of the lorry lifted from the road.

Low-Speed Behavior

Incidents at low speed cause particular problems in the interpretation of tachograph data because all instruments have a level below which they do not record speed. In all current models, this is about 5 km h^{-1} , although in some older instruments it is somewhat higher, up to 16 km h^{-1} . Therefore, it can neither be said, for example, whether a vehicle that has slowed before entering a main road actually stopped or merely reduced its speed to, say, 5 km h^{-1} before proceeding nor may it be possible to say whether or not during an apparent stationary period the vehicle was moved a small distance.

Some information can, however, be gained from the mode-of-work trace. Movement of the vehicle generates a thicker line, made by an oscillation, or an increased oscillation, of the recording stylus (see the examples in [Figure 1](#)). A small gap in the thick line can be taken as a brief stationary period. The threshold for this thick line depends on the model. Mechanical

Figure 14 Spin up in roll-over.

instruments will produce a noticeable movement in the stylus only when the vehicle has moved for about 20 m or more. Electronic instruments have a critical speed at which the line is made. The mode trace in Kienzle 1318 and 1319 instruments, however, operates during driving in the same way as the zigzag distance trace, making one stroke over a distance of 50 m.

Falsifications and Diagnostic Signals

Tachographs have always been prone to attempts by drivers to falsify the recordings, to show either lower speeds or shorter hours of work. Most falsifications are readily apparent on careful examination, for example, by comparing the apparent average speed during a journey with the recorded distance and the time taken, or by comparing the total recorded distance for the day's driving with the difference in the hand-written odometer figures. [Figure 15](#) shows a commonly attempted falsification, where driving has stopped at 1736, the clock has been rewound, and driving has resumed, apparently earlier, at 1623.

The scope for such tampering is greatly increased with electronic instruments, and therefore, various 'diagnostic' features are incorporated in them to show when certain irregularities occur. These depend on the individual models of instrument, and a full account of them is beyond the scope of this article. However, two examples are as follows.

If the pulse sender is disconnected in an attempt to make it appear that the vehicle is not being driven, the speed stylus will oscillate between zero and, typically, 30 km h^{-1} to make a broad band ([Figure 16](#)).

Figure 15 Fraudulent rewinding of tachograph clock. The overlapping traces show that the time was turned back from 1736 to 1623 h.

Figure 16 Broad trace generated when speed transducer is disconnected.

If the electrical supply to the instrument is interrupted, in an attempt to halt recording for a period, then, on reconnection, the speed stylus will execute a characteristic movement, for example, a full-scale deflection or a dip to zero speed.

Other attempts at falsification, that can be more difficult to detect, include connecting the wires from the pulse sender to earth; reducing the voltage to the tachograph, such that the clock continues to operate but the other electronic systems fail; and connecting certain spare terminals on the back of the instrument together, again to cause some of the electronic functions to fail.

Case Example

Figure 7 is an enlarged section of a tachograph recording made by a tourist bus that came into collision with a pedal cycle. The bus had been on a slip road, approaching a main dual-carriageway road. The pedal cyclist was traveling on the main road and appears to have cut suddenly across the path of the bus. The bus driver braked hard and swerved to his right. **Figure 17** shows the route the bus had taken to the scene of the accident.

The results of the detailed analysis, given in **Table 1** and plotted in **Figure 8**, indicate that (point *i*) about 120 s before the accident the speed of the bus was at a minimum of 19 km h^{-1} and that it was about 1900 m from the scene of the accident. Its speed then increased to a maximum (points *f* and *e*) of 71 km h^{-1} before falling to another minimum (point *d*) of 38 km h^{-1} . It was then about 67 s and 1110 m from the end.

Again the speed increased, reaching its final maximum (point *b*) of 81 km h^{-1} immediately before the collision. There was then heavy braking to a sudden disturbance of the trace (point *a*), which on the chart is at an indicated speed of 60 km h^{-1} . However, the time interval between *a* and *b* is too small to measure, and at the scene, locked wheel skid marks were found from the rear wheels on one side of the vehicle. The rapid fall of the recording trace between the last two points has clearly occurred as a result of the locking of these driven

wheels, which accounts for the immeasurably small time interval and also means that the figure of 60 km h^{-1} (because of the characteristics of the particular instrument) is probably significantly less than the speed at which the disturbance occurred.

The disturbance itself consists of a thickening of the trace, caused by a small shock to the stylus, followed by a step to the left (i.e., 'backward' in time). The shock would have been caused by the impact at the front of the bus with the pedal cycle, whereas the sudden swerve would have brought about some sideways movement of the components of the tachograph instrument, to create the step to the left.

Route Tracing

The two minima of speed in **Table 1** lie at distances from the end, which, on an accurate map, can be readily identified with a roundabout (point *d*) and an intersection (point *i*). When the analysis is extended back to the start of the driving, two further minima and the start of the journey itself can be matched to a complex road junction and two more roundabouts (points *j*, *k*, and *l* in **Figure 7**). Some very slow driving before point *i* indicates that the bus started its driving from a place just before the roundabout.

In the context of a road accident, the matching of the trace to a known route serves to confirm the accuracy of the analysis process and of the calibration of the tachograph installation. If it had not been possible to check the calibration independently, this matching, with any necessary adjustment of the speed figures, could have been used as a calibration procedure in itself.

However, if it is imagined that, in different circumstances, the route of the vehicle was unknown, and there was a need for it to be found, it can be seen that working back from the known end point (*a*), it would be possible to do so by comparing distances between speed minima with distances on a map between road junctions. A typical case where this method is applied would be where a vehicle carrying a valuable load is stolen from a known location *X*, driven to an unknown place *Y* and unloaded, and then driven to a third place *Z* and abandoned. From its tachograph record, it may be possible to locate *Y* by tracing back from *Z* or forward from *X*. The success of this method depends on traffic conditions; in heavy traffic, the vehicle may have had to stop so many times at places other than road junctions, where following its route becomes impossible.

Digital Tachographs

EEC Regulations now require that from May 2006, all tachographs fitted to vehicles that fall within their scope be of the digital rather than analog type. Digital tachographs make their recording on a removable 'smart card' rather than a paper chart, although a printer within the instrument also provides a summary of some of the data on a paper strip. Digital tachographs have similarities with the event data recorders (EDRs) fitted to some vehicles. Current models of digital tachograph include Siemens VDO DTCO1381, Stoneridge SE5000, and Actia SmarTach L2000.

Figure 17 Section of Ordnance Survey map showing route of vehicle as determined from the tachograph recording in [Figure 7](#) (Crown copyright reserved).

The specifications to which they all conform require, among other things, that speed is recorded with a resolution of 1 Hz and that the smart card holds the record for the last 24 h of driving (not simply the last 24 h of time). The 1 Hz record of earlier driving is deleted, although simplified data are still held on times and distances traveled and maximum speeds. But manufacturers may choose to exceed the specifications, and, for example, the Siemens VDO DTCO1381 holds a record of the speed at 4 Hz for the xx seconds preceding the last stop made by the vehicle.

The reader is referred to EEC Regulation 1360/02, manufacturers' literature and the article on EDRs for further information.

Glossary

Decision errors These errors represent intentional actions that proceed as intended, but the plan proves inadequate or unsuitable for the situation. Usually, they are related to knowledge, problem solving, and procedural errors, such as improper procedure, exceeded ability, and poor decision.

Error Normal accepted behavior that fails to meet the desired outcome.

Human Factors In 2000, the International Ergonomics Association defined ergonomics (human factors) as “the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and other methods to design in order to optimize human well-being and overall system performance.”

Perceptual errors These errors can occur when the operator has perceived features of the environment

inaccurately (sensory degradation); the misperception could be visual, auditory, olfactory, etc. Mostly they are related to detection, awareness, and understanding errors, such as distance misjudgments and visual illusion.

Skill-based errors These errors represent unintended/unconscious behaviors of operators, which usually occur in the operator's execution of a highly practiced task relating to procedure or a routine. In general, they are related to attention failures, memory lapses, and inadequate techniques, such as an omitted step in procedure, an omitted checklist item, and poor technique.

Violation Refers to the willful disregard of accepted practices and norms within a field of endeavor. The keyword is willful; that is, the individual knew what the accepted practice was but chose to ignore it.

The need to manage human error comes as no great revelation to anyone involved in operations where the consequences of failure are dire. Truth be told, however, the ‘battle cry’ that human error is associated with some 60–80% of all accidents/incidents in complex, high-risk systems has become passé in many organizations. The reason behind this attitude is that human error statistics have not changed appreciably in more than half a century. While safety professionals can all agree that something ‘must’ be done to reduce errors, a growing number of executives in the boardroom are becoming skeptical of the idea that something actually ‘can’ be done.

So where does one start when managing human error? Most quality and safety professionals are very familiar with the traditional system safety approach illustrated in Figure 1. While there are many variants to the approach, most involve the following components: collecting relevant data, identifying and assessing hazards, identifying/developing interventions, assessing intervention feasibility, implementing intervention, and system monitoring/program evaluation. Ideally, this is a dynamic process involving the real-time identification of threats, deployment of interventions, and, hopefully, improvements in the process.

Historically, this traditional approach to system safety has been effective in addressing mechanical and engineering problems within a variety of operational contexts; however, it has been facilitated by the development of a set of engineering tools and techniques for implementing each step. Not surprisingly, given the success of system safety in the engineering world, many quality/safety professionals have been quick to adopt this same approach when attempting to manage complex human factors issues.

Unfortunately, the requisite tools and techniques for employing system safety concepts within human factors have been largely ineffectual or nonexistent. As a result, it has been virtually impossible to get beyond the first step in the process – data collection. In fact, when an accident or incident does happen, the most common response is to simply collect more data. However, merely gathering more data about the occurrence of errors is ‘not’ the solution. In fact, most quality and safety departments are already swimming in data, particularly given the recent advances in technology that have increased the amount of information available.

As a result, those tasked with solving the human error dilemma have become frustrated with just watching the ‘data bucket’ fill up while having no means to interpret the information contained within the bucket. After all, implementing intervention programs that improve safety is the ultimate goal, and one should not confuse data collection with interventions.

Rather than systematically analyzing the aggregate data for significant trends, the modus operandi of many organizations has been to simply ‘cherry pick’ the hazards identified in the most recent incident or focus on select ‘high profile’ events that have captured everyone’s attention, thereby bypassing the next two critical steps in the system safety process and jumping right on to identifying interventions (see Figure 2). However, these may have no real bearing on the more significant systemic hazards.

To make matters worse, there are few tools for systematically generating effective intervention programs that target specific forms of human error. Consequently, quality/safety professionals have been forced to bypass two more crucial steps in the safety management process – generating and

Figure 1 The safety management process.

evaluating intervention strategies (see [Figure 2](#)). Indeed, the typical process for ginning up error prevention programs is to use simple intuition, expert opinion, or 'pop psychology.' Unfortunately, such an approach often results in people pushing their pet projects, or the person with the highest authority having the last say on what gets done. Hence, this entire system engineering approach to human error management, although conceivably a good idea, has met with little success.

Over the last decade, human factors psychologists and engineers have been working on ways to improve the human factors system safety process by developing human factors tools and techniques. The remainder of this article describes one of the tools born out of aviation accident investigation to facilitate error identification and intervention development within the context of forensic science.

HFACS – A Human Factors Investigative Tool

It is generally accepted that human error is not the isolated act of a particularly unlucky individual. Rather, it is the result of a chain of events that often culminate in a less than desired outcome. This is not particularly new, as industry has embraced a sequential theory of human error for nearly a century. However, some would argue that it was not until James Reason published his 'Swiss cheese' model of human error in 1990 that industry truly began to examine human error in a systematic manner.

Figure 2 Lack of effective human factors tools results in key steps in the safety process being skipped.

Reason's approach to error causation is based on the assumption that there are fundamental elements of all organizations that must work together if safe and efficient operations are to occur. Taken together, these elements comprise a 'productive system' as depicted in [Figure 3](#). For example, forensic analysis can be viewed as a complex productive system whose 'product' is the identification and classification of forensic evidence. These so-called 'productive activities,' in turn, require the effective integration of human and mechanical elements within the system, including, among other things, an effective scientist-laboratory interface to ensure optimal performance.

Even before productive activities can occur, certain 'pre-conditions,' such as reliable and well-maintained equipment and a well-trained and professional workforce, need to exist. After all, most analysts work within a highly structured organization that requires effective middle management and careful supervision. Furthermore, such management and supervision is needed across numerous departments within the larger organization. But even the best managers need guidance, personnel, and money to perform their duties effectively. This support comes from decision makers who work even further up the chain of command, charged with the responsibility of setting goals and managing the available resources of the organization.

In most organizations, this highly structured and orchestrated system functions well. However, what about those rare occasions when the wheels do come off? According to Reason, accidents occur when there are 'breakdowns' in the interactions

Figure 3 Components of a productive system.

among the components involved in the production process. These failures degrade the quality of the system making it more vulnerable, and hence more susceptible, to erroneous conclusions. As illustrated in [Figure 3](#), these errors can be depicted as 'holes' within the different layers of the system, which transform what was once a productive system into a failed or broken-down process. Given the image of Swiss cheese that this illustration generates, the theory is often referred to as the 'Swiss cheese' model of error causation.

So, what are those 'holes in the cheese' or failure points in the system? Drawing upon Reason's concept of latent and active failures, the Human Factors Analysis and Classification System (HFACS) describes human error at each of four levels: (1) the actions of the operators (e.g., bench-level scientists and field investigators in forensics), (2) the preconditions for those actions (i.e., the conditions that influence human behavior), (3) the middle management (i.e., the individuals whose role it is to assign work), and (4) the organization itself.

In other words, the HFACS framework goes beyond the simple identification of 'who did what wrong' to provide a clear understanding of the reasons 'why' the error occurred in the first place. In this way, errors are viewed as consequences of system failures and/or symptoms of deeper systemic problems, and not simply as the fault of the examiner whose fate was tied to being at the 'pointy end of the spear.'

HFACS was originally developed and used as an aviation accident investigation and analysis tool for the U.S. Navy and Marine Corps. Since then, the framework has been adopted by a number of other aviation, transportation, and high-risk industries. More recently, HFACS has been modified by the Expert Working Group on Human Factors in Latent Print Analysis chartered by the National Institute of Standards and Technology for use in forensic science. The brief discussion that follows is a product of that effort.

Analyst Actions

The actions of the forensic analyst can be loosely classified as either errors or violations (see [Figure 4](#)). While both can occur within most settings, they differ markedly when the rules and regulations of the scientific field are considered; that is, while errors represent normal accepted behavior that fails to meet the desired outcome, violations refer to the 'willful' disregard of accepted practices within the field. It is within these two overarching categories that HFACS describes three types of errors (decision, skill-based, and perceptual) and types of violations.

Decision errors

Successful decision making depends upon three fundamental ingredients: (1) information – that is, information (e.g., fingerprints, DNA) must be of high quality and other variables such as the surface from which the evidence was obtained must be known; (2) knowledge – analysts must have the necessary knowledge, training, and background to reliably assess the information provided; and (3) experience – there is ample evidence in the literature that suggests that experience also contributes to decision making. Ultimately, when information, knowledge, or experience is lacking or degraded, errors can occur. Often referred to as honest mistakes, errors typically manifest as poorly executed procedures, improper choices, or simply the misinterpretation and/or misuse of relevant information (see [Table 1](#)).

Skill-based errors

In contrast to decision making, skill-based behavior occurs with little or no conscious thought. For instance, little thought goes into turning one's steering wheel in an automobile or

Figure 4 The Human Factors Analysis and Classification System (HFACS).

typing on a keyboard. Likewise, in latent fingerprint examination, most analysts orient latent prints for examination with little or no conscious thought. In other words, they do not have to think about it – they just do it. The difficulty with these highly practiced and seemingly automatic behaviors is that they are particularly susceptible to attention and/or memory failures. Unfortunately, even the technique or ‘skill’ with which we do a task can lead to erroneous conclusions (see [Table 1](#)).

Perceptual errors

While decision and skill-based errors are the most common error forms seen in occupational settings, perceptual errors may also impact the forensic laboratory. No less important, these ‘perceiving’ errors arise when sensory input is degraded, or ‘unusual.’ For example, latent fingerprint analysis is a decidedly visual comparison task that requires optimal visual conditions to insure accuracy and reliability. Consequently, laboratory environmental factors such as the intensity, type, and

Table 1 Selected examples of analyst actions

<i>Errors</i>	<i>Violations</i>
<i>Decision errors</i>	
● Improper orientation of data ● Print improperly deemed unsuitable ● Printer improperly deemed suitable ● Improper anatomical source of data ● Poor target group selection ● Hurried examination ● Thorough analysis not conducted ● Incomplete search ● Failure to search all exemplars ● Misprioritized level of effort ● Failure to use available technology ● Conclusion exceeded ability of examiner ● Insufficient data to support conclusion ● Failure to recognize exemplars are insufficient/inadequate	● Intentionally issue an unsupportable conclusion ● Failure to follow SOPs ● Refusal to use available technology ● Consistently failed to mark a difficult print ● Consistently conduct an incomplete search ● Failed to maintain objectivity
<i>Skill-based errors</i>	
● Poor search technique ● Incomplete comparison due to failure of memory ● Incomplete comparison due to attention failure ● Failure to recognize distortion (i.e., variation in appearance) ● Failure to properly weigh the significance of the data ● Failure to find target ● Inability to reach a conclusion ● Misinterpreted the data ● Distraction	
<i>Perceptual errors</i>	
● Failure to perceive due to poor contrast ● Visual illusion in print	

Note: This is not a complete listing.

direction of lighting can influence what an analyst perceives as key features of a print. When confronted with less than ideal conditions, an analyst may perceive that there is more or less information in a given print than there actually is (see [Table 1](#)).

Violations

Although there are many ways to distinguish between types of violations, two forms have been identified based on their etiology. The first, routine violations tend to be habitual by nature and are often enabled by a system of supervision and/or management that tolerates such departures from the rules. Often referred to as ‘bending the rules,’ the classic example is that of the individual who drives his/her automobile consistently 5–10 mph faster than allowed by law. While clearly against the law, the behavior is, in effect, sanctioned by local authorities (police) who often will not enforce the law until more excessive speeds are observed. What’s more, speeding on the interstate is something that most people do, and often it becomes a ‘routine’ part of the individual’s behavior.

In contrast, driving at 120 mph in a 55-mph zone would be considered an exceptional violation. It is important to note, that while most exceptional violations tend to be particularly dangerous, they are not considered ‘exceptional’ because of their extreme nature. Rather, they are regarded as exceptional because they are neither typical of the individual(s) nor condoned by management. In essence, they are ‘exceptions’ to normal behavior.

Unfortunately, depending on the setting and conditions an individual is faced with, what may be a routine violation in one

organization or situation may be an exceptional violation in another. For instance, driving 5–10 mph over the speed limit on a US interstate may be condoned by local authorities and is done by most people, while driving that same 5–10 mph over the posted speed limit in a school zone certainly would not be condoned nor does everyone do it. Likewise, depending on the given laboratory procedure, a violation may be perceived as routine (everyone does it) or exceptional (rarely occurs). Often, the actual causal factor (e.g., failure to follow standard operating procedures (SOPs)) is the same in both categories, only the circumstances surrounding the violation are different. Consequently, all violations are simply included within one category as shown in [Table 1](#).

Preconditions Analyst Actions

Simply focusing on errors, however, is like focusing on a medical patient’s symptoms without understanding the underlying disease state that caused it. As such, investigators must dig deeper into the preconditions for why errors occurred. Within HFACS, seven causal categories within three major subdivisions are described (see [Figure 4](#) for an illustration and [Table 1](#) for examples within the forensic sciences) ([Table 2](#)).

Adverse mental states

It is well known that human performance is affected by the mental state of the individual. Attitudes such as frustration, anger, and even misplaced motivation have all led to decision

Table 2 Selected examples of preconditions of unsafe acts

<i>Condition of analyst</i>	<i>Personnel factors</i>	<i>Environmental factors</i>
<i>Adverse mental states</i> ● Overconfidence ● Lack of confidence ● Distraction ● Mental fatigue ● Apprehension with reaching a conclusion ● Preoccupation with personal problems ● Task overload ● Frustration ● Channelized attention ● Complacency ● Misplaced motivation ● Stress ● Expectancy ● Boredom ● Anger ● Peer pressure ● Haste ● Bias ● Compromised integrity/ethics <i>Adverse physiological states</i> ● Medical illness ● Impairment due to drugs or alcohol ● Physical fatigue ● Eye strain <i>Physical/mental limitations</i> ● Performance limiting physical condition ● Visual limitations ● Dyslexia ● Color vision deficiency ● Chronic psychological disorder ● Incompatible intelligence/aptitude ● Limited experience/proficiency	<i>Communication and information flow</i> ● Failure to convey adequate information ● Failure to use all available resources ● Lack of teamwork ● Confusing/conflicting directions/demands ● Inadequate communication with management ● Inadequate communication between shifts ● Lack of communication ● Standard terminology not used ● Lack of report writing skills/poor documentation <i>Fitness for duty</i> ● Lack of sleep ● Self-medicating with prescription or over-the-counter medications ● Use of illicit drugs and alcohol ● Suffering from hangover ● Inadequate nutrition ● Reporting for work in ill-health	<i>Physical environment</i> ● Workspace design ● Inadequate lighting ● Inadequate ventilation ● Noise interference ● Excessive heat or cold ● Clutter <i>Technological environment</i> ● Inadequate/outdated ● Software or equipment ● Defective equipment ● Defective tools ● Inadequate information technology ● Confusing manuals

Note: This is not a complete listing.

and skill-based errors when not recognized and addressed by individuals. Likewise, cognitive states such as inattention, distraction, and task overload have all resulted in a variety of errors. Indeed, one of the more insidious adverse mental states is fatigue and stress associated with many occupations. Consider, for example, a forensic analyst who is called to a crime scene in the middle of the night and is then expected to show up the next day to attend to his or her normal caseload. Can management reasonably expect performance to remain at optimal levels? Likewise, the stress associated with working through large backlogs with limited resources or unrealistic quotas and turn-around times set by well-meaning, but uninformed, managers can lead to errors.

Adverse physiological states

Equally important, however, are those adverse physiological states that affect performance. The traditional work environment for many forensic scientists includes a standard desk, a magnifier or two, general lighting, and a variety of specialized tools with the analyst bent over a desk sifting through evidence to draw their conclusions. The strain on the neck and back can be considerable and may impact their performance. Likewise, many comparisons today are performed utilizing

computer monitors, which may expose the analyst to monitor glare, resulting in headache or eyestrain. Medical illness is also known to have an impact on performance; yet, people sometimes go to work with illnesses, such as a cold, migraines, or the flu, or worse, they are self-medicating with remedies that can adversely influence their decision-making ability.

Physical and/or mental limitations

Physical/mental limitations include those instances when an individual simply may not possess the necessary aptitude, physical ability, or skill to conduct an examination adequately. After all, just as everyone cannot play linebacker for his or her favorite professional football team or be a concert pianist, not everyone has the aptitude or physical attributes necessary to be a forensic examiner. Moreover, physical and mental aptitudes change as we age. Left unabated, normal aging processes can adversely influence performance.

Communication and information flow

Communication and information are essential to case management. The analyst must effectively work with a variety of analysts, managements, investigators, and attorneys. Indeed,

coordination among multiple ‘players’ (i.e., analysts, detectives, and the district attorney) is essential in case management. Poor communication will drastically reduce gathering of the necessary information that may affect casework. Case documentation is another mode of communication critical during technical review and for archival purposes.

Fitness for duty

Individuals, must, by necessity, ensure that they are adequately prepared for work. Consequently, this category was created to account for those instances when examiners do not get enough rest, report to work when ill, or take medications that may impair their ability to perform their duties.

Physical environment

The term physical environment refers to things such as heat and lighting toxins in the workplace, all of which are well known to impact human performance.

Technological environment

The technological environment that individuals often find themselves in can also have a tremendous impact on their performance. The term technological environment encompasses a variety of issues including the design of equipment and controls, display/interface characteristics, checklist design, and automation, to name a few. One needs to look no further than the design of automobiles to see poor design influencing performance. After all, who has not tried to turn on the lights in a rental car only to see the wipers engage instead? Similar

design flaws in the laboratory can be catastrophic. Whether one is having difficulty operating a DNA sequencer or dealing with flawed software, how one designs equipment can have a dramatic influence on analyses and interpretation of complex results.

Middle Management

Ultimately, analysts and those at the front lines of forensic science are responsible for their actions. However, in some instances, they are the unwitting recipients of a variety of latent failures attributable to those who manage them. To account for these threats to quality, the overarching category of ‘supervision’ was created within which four categories (leadership, operational planning, failure to correct known problems, and supervisory ethics) are included (Table 3).

Leadership

At a minimum, supervisors must provide the analysts in their charge the opportunity to succeed. Toward these ends, it is expected that effective leaders will provide analysts with adequate training, professional guidance, oversight, and operational leadership, and that all will be managed appropriately. When this is not the case, examiners can become isolated, thereby increasing the likelihood that errors will occur. For example, it is not difficult to imagine a situation where a manager becomes so overwhelmed with answering e-mail, attending telecons, preparing countless presentations, etc. that they fail to provide sufficient oversight of their analysts.

Table 3 Selected examples of middle management

Inadequate supervision

- Lack of appropriate incentives
- Inadequate performance measurement evaluation
- Unrealistic expectations
- Insufficient initial or ongoing training
- Inadequate assessment of required skills
- Failure to track job qualifications/skills
- Lack of coaching/training on skills
- Change introduced without training
- No measurement of training effectiveness
- Inadequate leadership job knowledge
- Inadequate monitoring of work
- Personality conflicts between manager and employee
- Failed to provide professional guidance/oversight
- Failed to set a proper example

Operational planning

- Unclear/conflicting assignment of responsibility
- Inadequate communication of policy, procedure, practices, and/or guidelines
- Improper/insufficient delegation of work
- Setting objectives, goals, or standards that conflict
- Improper/insufficient delegation of work
- Setting objectives, goals, or standards that conflict
- Failure to provide adequate rest breaks
- Inadequate matching of individual qualifications and job/team requirements
- Unrealistic deadlines or quotas
- Inadequate documentation

Failed to correct a known problem

- Failure to correct known workplace hazard
- Improper performance is rewarded or tolerated
- Failure to correct inappropriate behavior (hostile work environment)
- Failure to initiate corrective actions
- Failure to correct known reportable problem
- Failure to update/revise operator guidelines, policies, and procedures

Supervisory ethics

- Management implied haste
- Undue influence toward a desired outcome
- Violation of operating guidelines, policies, and procedures by a manager
- Manager encourages bending of the rules
- Enabling excessive risk taking
- Failure to enforce rules and regulations
- Fraudulent documentation

Note: This is not a complete listing.

In the end, the employees are left with little guidance and oversight, as the 'phantom manager' is lost in an electronic world of corporate demands. In contrast, some supervisors take oversight to extremes, becoming overcontrolling and more concerned with minute details rather than the accuracy of the work. In effect, by micromanaging their analysts, decision making is often delayed, information flow between employees is often restricted, and overall confidence and efficiency can be diminished.

Operational planning

The risks associated with failures of management and supervisors come in many forms. For example, occasionally the operational tempo and/or schedule are planned such that individuals are put at unacceptable risk and, ultimately, performance is adversely affected. As such, the category of operational planning was created to account for all aspects of improper or inappropriate scheduling practices, which may involve such issues as, rest breaks, workload, deadlines, etc. Consider, for example, the supervisor who assigns a complex case to a junior or less-experienced analyst rather than someone with more experience who may be more capable. In some ways, the supervisor may 'set up' the analyst for failure. Likewise, it is not uncommon for supervisors and management to continue to 'go to the well' and overload the high performer while ignoring those who are less capable or difficult to work with. In either event, the top performers are often burdened with additional work and in some circumstances may be prone to error when they would otherwise perform optimally.

Failure to correct known problems

The remaining two categories of unsafe supervision, the failure to correct known problems and supervisory ethics, are similar, yet considered separately within HFACS. The failure to correct known problems refers to those instances when deficiencies among analysts, equipment, training, or other related safety areas are 'known' to the supervisor, yet are allowed to continue uncorrected. For example, the failure to consistently correct or

discipline inappropriate behavior fosters an unsafe atmosphere but is not considered a violation if no specific rules or regulations were broken. Similarly, there are times when optimal equipment is not purchased or necessary repairs are not done on existing equipment, yet the mission can still be carried out – just not as efficiently or without undue burden on analysts.

Supervisory ethics

This category is reserved for those instances when supervisors willfully disregard existing rules and regulations. While everyone would agree that putting undue influence on forensic analysts toward a desired outcome is clearly an example of poor supervisory ethics, more subtle ethical violations can result in adverse outcomes in the forensic laboratory. For instance, permitting unqualified forensic analysts to do casework can lead to errors that may go unnoticed. Likewise, encouraging the bending of rules and procedures in the interest of reducing backlogs is a classic failure of supervisory ethics.

Organizational Influences

Where decisions and practices by laboratory supervisors and managers can adversely impact forensic analyst performance, fallible decisions of upper-level management may directly affect the supervisors and the personnel they manage. Unfortunately, these organizational influences often go unnoticed or unreported by even the best-intentioned quality assurance personnel. Within this tier, the HFACS framework describes three organizational failures: (1) resource management, (2) organizational climate, and (3) operational processes (Table 4).

Resource management

This category refers to the management, allocation, and maintenance of organizational resources, including human resource management (selection, training, and staffing), monetary budgets, and equipment design (ergonomic specifications). In general, corporate decisions about how such resources should

Table 4 Selected examples of organizational influences

Resource management

- Selection of personnel
- Inadequate evaluation, promotion, upgrade policies
- Inadequate hiring, firing, and promotion policies
- Staffing/manning issues
- Inadequate matching of qualifications for job
- Use of inadequate contractor/vendor
- Ineffective cost cutting
- Unfunded directives
- Lack of logistical support
- Failure to correct known design flaws
- Purchasing unsuitable equipment/parts

Organizational climate

- Inaccessibility/visibility of upper management
- Inadequate formal accountability for actions
- Unclear/conflicting assignment of responsibility
- Dysfunctional organizational culture
- Organizational values not clearly defined or articulated

Organizational process

- Work/production schedules that produce bad decisions
- Overextending resources
- Unrealistic quotas
- Organizational induced time pressure
- Lack of appropriate standards, policies, or guidelines
- Procedures not integrated into training process
- Quality process not adequately implemented/maintained
- Inadequate/inappropriate performance measures
- Failure to maintain accreditation

Note: This is not a complete listing.

be managed center around two distinct objectives – the quality of the analyses and on-time, cost-effective operations. In times of prosperity, both objectives can be easily balanced and satisfied. However, there may also be times of fiscal austerity that demand some give and take between the two. Unfortunately, history tells us that quality is often the loser in such battles, as quality improvements and training are often the first to be cut in organizations experiencing financial difficulties.

Organizational climate

The concept of an organization's climate has been described in many ways; however, here it refers to a broad class of organizational variables that influence worker performance. For example, one telltale sign of an organization's climate is its structure, as reflected in the chain of command, delegation of authority and responsibility, communication channels, and formal accountability for actions. Likewise, an organization's policies and culture are also good indicators of its climate. Consequently, when policies are ill-defined, adversarial, or conflicting, or when they are supplanted by unofficial rules and values, confusion abounds, and safety suffers within an organization.

Operational process

Finally, operational process refers to formal processes (operational tempo, time pressures, production quotas, etc.), procedures (performance standards, objectives, etc.), and oversight within the organization. Poor upper-level management and decisions concerning each of these organizational factors can also have a negative, albeit indirect, effect on operator performance and system safety.

Using HFACS to Identify and Address Threats to Quality and Safety

As described earlier, identifying what went wrong without fully understanding why it happened can lead to ineffective interventions/mitigation strategies. Consider, for example, a forensic analyst who inadvertently forgets to document a key step in the analysis, leading to an erroneous conclusion. On the surface, management might view such an error as unforgivable and resort to some form of admonishment or worse. However, without knowing 'why' the analyst forgot to document the key step, one cannot recommend a practical intervention apart from one that may appease those looking for some degree of accountability.

On the other hand, had a full human factors analysis been conducted, management might have uncovered the following:

1. *The analyst had been working overtime for several consecutive days (operational planning) in an attempt to relieve an extensive backlog of cases that had accumulated leading to fatigue (adverse mental state) and stress (adverse mental state).*
2. *The analyst had recently welcomed their first baby into the family and was still not sleeping through the night while off-duty (fitness for duty).*
3. *With the holidays fast approaching, the analyst was busy making holiday travel plans including airline reservations, with a*

newborn and conflicting work schedules, thereby compounding the stress he was undergoing (adverse mental states).

4. *Due to budget cuts (resource management), the staff was reduced by 20% resulting in an increase in workload (adverse mental state) without necessary support.*
5. *In an effort to reduce the workforce, management chose to offer the employees early retirement as an incentive to retire, resulting in the more experienced analysts retiring early (resource management).*
6. *The analyst who forgot to document the key step in the analysis was relatively new, with little experience in the field (physical/mental limitation) and would not ordinarily be tasked with such a complex and high-profile case (operational planning).*
7. *Because of the reduced staffing and increased workload (resource management), the analyst was not provided necessary training (leadership) and was given minimal oversight (leadership) during the investigative process.*

Arguably, such a scenario would likely change management's view of the necessary steps to prevent this sort of event from happening again. Moreover, punishment for such a transgression clearly would not have prevented the error from occurring in the future. Indeed, it is well known that one cannot punish one's way out of an error. If anything, punishment drives reporting underground and hampers safety and quality.

What makes frameworks such as HFACS effective is that each of the causal categories is based upon years of human factors research and has very specific interventions associated with it. For example, if one is trying to address decision errors, effort should be aimed at ensuring that useful and complete information is available, and that the analyst has acquired the knowledge to deal with the information through training and the requisite experience to know when he or she may need additional training or assistance. Likewise, if one were trying to address skill-based errors, efforts should be aimed at reducing distractions, ensuring that critical items are addressed through either checklists or other memory aids and that the initial and recurrent training is sufficient to ensure the skill and proficiency of the analyst.

Closing Thoughts

The field of human factors accident investigation and quality management is a rich and growing discipline with a history dating back decades. Recently, with the integration of tools such as HFACS into traditional system safety models, management in general and forensic management in particular are better able to identify and address heretofore unknown human causal factors. Of note, however, while special emphasis was placed on HFACS in this short article, there are many other tools and techniques available to those interested in human factors accident investigation.

The interested reader is encouraged to reach out to organizations such as the Human Factors and Ergonomics Society at www.hfes.org for more information.

Railroad Accident Investigation and Reconstruction

RW Halstead, IronWood Technologies, Inc., Syracuse, NY, USA

© 2013 Elsevier Ltd. All rights reserved.

Introduction

This article provides a broad introduction to the field of railroad accident investigation and reconstruction. The above term 'investigation' denotes the manner in which the scene of a railroad-related accident is secured and relevant forensic data collected and preserved, whereas 'reconstruction' denotes the application of scientific principles and analysis to the data collected so as to determine with the greatest degree of precision possible:

1. The sequence of factors that led up to the accident.
2. Whether the accident could have been prevented or its severity reduced through improvements in operating procedures, engineering design, or maintenance practices.

The 'investigator' and 'reconstructionist' may be, and often are, the same person. The final railroad accident reconstruction product may be used by governmental agencies contemplating additional regulatory activity or evaluating the effectiveness of existing regulations. It may be used by railroad companies to improve their internal engineering and operating procedures, and may be used to prosecute or defend criminal or civil legal proceedings.

Railroad accidents, as many other kinds of accidents, are rarely the product of a single factor or event, but most often result from a sequence of events, the removal of any one of which precludes the accident from occurring. Thus, it is incumbent on the railroad accident investigator and reconstructionist to cast a wide net for potential causal events; for any one of which might prove crucial to an understanding of an accident event, and its future prevention.

While this article is modeled on North American (primarily United States) operating and engineering practice, the investigative and reconstruction techniques set forth herein have broad application to the science of railroad accident reconstruction worldwide. As it is not possible to cover the entire breadth of the field of railroad accident investigation and reconstruction in any depth in this article alone, this article instead offers detailed information on a number of specific areas of interest in the field, while inviting the reader to pursue related information via supplemental sources.

Types of Railroad Accidents

Railroad accident investigators and reconstructionists may be called upon to examine a variety of railroad-related accidents, including but not limited to

- collisions between two or more trains (head-on, rear-end, sideswipe),
- derailments,
- collisions between trains and vehicles or pedestrians,
- platform gap injuries,

- electrocution (railroad employee or civilian), and
- railroad employee injuries (United States: Federal Employer's Liability Act).

Factors that may have contributed, in whole or in part, to the accident may include

- excessive speed by train crew or motorist;
- inadequate sight distance for train crews and/or motorists at level crossings around vegetation or standing equipment on adjacent tracks;
- operating rules noncompliance by train crews;
- train crew unfamiliarity with the section of track over which they were operating leading up to the accident;
- inadequate design and/or maintenance of track, level crossing surface, signaling systems for trains or motorists, or safety appliances on locomotive or cars;
- failure to thoroughly test signal system revisions or upgrades before placing in service;
- fatigue – train crew and/or motorist;
- impairment by drugs and/or alcohol;
- inability of motorist to accurately judge closing speed of train;
- motorist impatience at level crossings;
- improper operation of traffic signals at traffic intersections interconnected with active warning devices at level crossings; and
- failure to conduct safety briefing before performing task and/or failure to adequately supervise the performance of a potentially hazardous task.

Event Recorders

As time goes on and railroad signal and train control systems become more sophisticated, more and more systems are incorporating event-recording capability, many of which are useful to the accident reconstructionist.

Among the first sources of data typically pursued for preservation and analysis in a railroad accident, investigation is from the locomotives involved in the accident. In the United States, every leading locomotive (or cab car, if the train is being shoved by a locomotive at the rear) that exceeds 48.3 km h^{-1} (30 min h^{-1}) must be equipped with a functioning event recorder that must record at least the most recent 48 h of operation (49 CFR § 229.135a). Other countries may have their own event recorder installation and data retention requirements. The recorder may record data on a tape-based medium or in digital memory. Data extraction is usually performed through removal of a tape, memory module, or download of data to a laptop computer. Nonradar-based event recorders require the accurate measurement of the diameter of the wheel-set from which the recorder is receiving data in order to facilitate data analysis.

Data from the locomotive event recorder are often encrypted, and must be processed by the event recorder manufacturer's proprietary software for analysis. The date, time, and exact location of the locomotive at the time of data extraction should be noted, and a chain of custody document should be established and maintained as the data are handed off from person to person to the point of final analysis.

Locomotive event recorders typically sample their input channels and record data records in either a second-by-second manner or 'on demand' (only when one or more data input channels change state). Data input channels typically include time, speed, distance, throttle and braking status, and wayside signal aspects. Newer digital recorders accept more input channels than do the older tape-based units, and may include horn and headlight status and safety-critical messages from the train control system.

It is important to note that as the locomotive travels down the track, the (nonradar-based) event recorder samples its inputs and records data at its designed interval, but the recorder itself has no idea of where it is located along the track at the time at which each specific data sample is taken. In order to determine the train's location at specific times in the event recorder data, at least one specific event recorder data record must be correlated with a specific location along the track. This is commonly done by associating the point on the track at which the locomotive came to rest with the first event recorder data record that shows a speed of zero. Once correlated in this manner, the location along the track corresponding to any event in the event recorder data (brakes first applied, horn first sounded, etc.) can be quickly determined by adding or subtracting their corresponding distance values in the data.

Authentication of locomotive event recorder data can be accomplished by comparing the progression of the data over several kilometers or several tens of kilometers of territory before the collision point. Recorded speeds are compared to areas of known speed restrictions, horn soundings are compared to known level crossing locations, and stops (event records displaying a speed of zero) are compared with locations of known station stops to verify that the offered data most likely pertains to the subject accident, and that the recorded measurement of wheel size is reasonably accurate.

Increasingly, locomotive event recorders are being equipped with the ability to record GPS (Global Positioning System) coordinates corresponding to each individual data record. When present, GPS data offer a means of independent verification of the analysis detailed above.

If more than one locomotive or leading cab control car is involved in the accident, data from all available event recorders should be obtained. The resulting data sets can be cross-compared to ensure data integrity and verify the accuracy of the wheel diameter measurements used for data interpretation.

Additional data useful in a railroad accident investigation may be extracted from the following:

- Train dispatcher's computer logs – recording all dispatcher control inputs and resulting status indications from field signaling equipment, typically located in the main dispatching center.
- Telephone and radio audio recordings of voice transmissions from dispatcher to train, train to dispatcher, and train to train.
- Signal system computer logs – typically stored in the field by solid-state interlocking controllers or equivalent, and/or by computer-controlled level crossing control equipment.
- Nearby defect detectors – 'hot box' (overheated wheel bearings), flat wheel, dragging equipment, or excessive dimension (high/wide). Detectors often record not only the existence of a defect, but also the speed of the train at that instant for comparison with corresponding locomotive event recorder data.
- Automatic Equipment Identifier locations – scanners read magnetic tags on the side of cars as the train passes – gives a listing of each of the cars in the train (and their order) and the speed of the train as it passed through the scanner.
- Cellular telephone tower records – when obtained from the telephone company (in the United States, commonly referred to as 'Call Detail Records' and 'Cell Tower' and 'Switch' Records), they can be used to determine whether or not the train operator's cell phone was in use at a critical portion of the approach to the accident location. 'Smart phones' that internally record GPS positioning data can also be used to position the train and/or motorist at critical points in the approach to the accident, particularly in cases in which locomotive event recorder data do not exist or are unusable.
- Locomotive video – though not required in the United States (yet), more and more major railroads are equipping their locomotives with onboard video cameras. The cameras record to a computer hard drive, and are usually interfaced with the locomotive's existing event recorder.
- Surveillance video from surrounding cameras mounted on residential, commercial, or governmental structures that may have captured part or all of the accident scenes on video. Retention periods are typically short, and timely data recovery is essential.
- Motor vehicles – most modern airbag systems record pre-crash data related to the driver's speed, use of brakes and seatbelts, etc., in modules commonly referred to as an EDR (Event Data Recorder) or SDM (Sensing Diagnostic Module), that can be downloaded from the vehicle to a laptop computer through the use of specialized hardware and software.
- Motor vehicles – General Motors Corp. OnStar system or equivalent, if equipped, offers an independent record of the vehicle's GPS position as a function of time.

Once data are secured from all possible sources, it must be synchronized in order to assemble a comprehensive picture of the events leading up to the accident. To do this, a data source that uses the GPS time base is selected (if available), and all other data sources are synchronized to it by identifying one or more common events that appear across multiple event data sources, taking into account network delay and update frequency for each data source.

After all available event data have been accurately synchronized, a more complete picture of the events that led up to the accident begins to emerge. Movement of the respective vehicles can be plotted with respect to time, recorded precollision use of horn and braking can be evaluated, and the operation of the signal system can be recreated with a reasonable degree of accuracy. The synchronized event data can then be combined with physical evidence collected at the scene in a final analysis of the accident event.

Procedural Steps to Follow in Railroad Accident Investigation and Reconstruction

While there are many different kinds of railroad accidents, certain investigative procedures tend to be applicable to almost all. The generalized list below represents typical investigative activities, and is not intended to supersede more specific procedures that may already be in force in the locale in which the accident has occurred.

Collision with Motor Vehicle or Pedestrian

1. If the train is still at the scene, observe a demonstration of the leading locomotive or cab car's horn, headlight, ditch lights (if equipped), and bell.
2. Download the event recorder on every locomotive and cab car on the train. Note the exact time that the data were downloaded.
3. Download the video recorder on all equipped locomotives and cab cars.
4. Measure the distance from the point of impact to the front of the leading locomotive or cab car at rest. This distance value will be required to analyze the locomotive event recorder data. Mark the location of the front of the leading locomotive at rest on the side of the rail with a paint stick or equivalent, ensuring that that point will be preserved even after the train is moved.
5. Perform or observe testing of the active warning devices (flashers, gates, etc.) at the level crossing, if so equipped. Ensure that all governmentally required tests that apply to level crossing warning devices are performed, along with all additional tests required and customarily performed by the railroad entity that has primary maintenance and testing responsibility for the warning devices. Ensure that the results of all such testing comport with those expected for a nondefective, properly functioning system.
6. Download and preserve data from all computer-controlled warning device control equipment or auxiliary event recorders connected thereto.
7. Examine the pavement surface in the vicinity of the crossing – photograph, measure, and diagram all pavement gouges and tire skid marks attributable to the accident vehicle. Observe the condition of the pavement surface at the track for roughness, potholes, and so on.
8. If the level crossing is humped, take measurements sufficient to create a cross-sectional view of the crossing's profile, then compare its shape to generally accepted standards (United States: AASHTO standards).
9. Examine signage that governed the accident vehicle's approach to the collision for completeness, placement and visibility, and reflectivity (if at night).
10. Inspect the scene for the presence of vegetation or other fixed obstruction that may have impaired the motorist's ability to see down the track for approaching trains. If any is found, measure and diagram its relationship to the level crossing.
11. If the level crossing has active warning devices and they are interconnected with traffic signals at an adjacent intersection, perform or observe testing of the combined system to ensure that the traffic signals displayed the proper phases as required by the approach of the train.
12. Map the overall accident scene and debris field. Collect and analyze any debris that may have bearing on the accident, including all crossing signal equipment replaced immediately after the accident.
13. Collect statements from all eyewitnesses and others with potentially useful information.
14. Scan the area for security cameras oriented in the general direction of the level crossing. If any are identified, arrange to obtain the video footage from the time of the accident.
15. Collect the remains of any shattered light bulbs from the vehicle, locomotive, or crossing signals. It may be possible to perform a 'stretched filament' analysis on them to determine if they were lit at the instant of impact.
16. If the level crossing is equipped with gates, collect video footage depicting the gates going up and down repeatedly. Back in the office later, the video tape can be run in slow motion and very precise gate operating times can be determined.
17. Take lots of photographs and video footage from a variety of angles and distances from the crossing. Use a 50 mm lens for all photography – it most closely replicates the perspective of the human eye.
18. Secure audio file copies of all radio and telephone footage between the train crew and train dispatcher (if applicable) for the 5–10 min leading up to the collision.
19. Note the weather at the time of the accident, as well as sun angle.
20. If the level crossing was equipped with active warning devices, examine the incoming commercial power feed – determine if commercial power was on or off at the time of the accident.
21. Determine if the motorist/pedestrian/train crew employees were tested for the presence of alcohol or drugs.
22. Determine if cell phones were in the possession of and/or were in use at the time of the accident.

Collisions Between Trains

Though their frequency has greatly decreased over the years through the increased use of advanced technology and operating practice refinement, train collisions still occur in the United States and around the world. Potential collision causes include

1. Train dispatcher mistakenly authorized two trains to occupy the same block of track simultaneously.
2. One or both train crews incorrectly interpreted track block authority, leading them to enter a section of track for which they had no authorization to occupy.
3. Signal system failed by displaying a 'false clear' signal to one or both trains, a signal conveying information that was more favorable than intended. Alternatively, the proper signal was displayed but was misinterpreted by the crew due to sun glare or other missed vision cue.
4. Signal system functioned properly, but train crew failed to observe and/or act on restrictive signal information due to inattention, fatigue, or drug or alcohol impairment.
5. Braking system failure occurred on one or both trains.
6. Excessive speed by one or both trains, leading to an inability to stop short of a restrictive signal as required.

When the collision occurs in territory that is equipped with a signal system, all available signal system event recorders must be downloaded, and their data content synchronized and carefully interpreted to determine if any 'false clear' signals were displayed to the accident crews. In addition, complete post-accident 'service testing' must be performed on the signal system, in which all possible combinations of train routings, including those being conducted at the time of the accident, are simulated and the signal system outputs are compared to those intended.

Derailements

Derailements may be caused by track defects, equipment defects, signaling defects, poor train handling or other human factors, improperly loaded freight, improper train makeup (heaviest cars at rear of train), or any combination of these factors.

Upon arrival at the accident scene, an investigator will typically begin at the location of the wreckage and walk down the track opposite the train's direction of travel, looking along the rails and track structure for the point of derailment (POD). This is the first evidence of a wheel climbing the rail, commonly seen as a prolonged scuff or scrape mark along the top of the rail, followed by spike and tie damage as the wheel flange contacts and begins to ride along the top of the tie plates or ties. While the initial POD is commonly found within 100 m or so of the general wreckage, it may also appear up to several kilometers from the main wreck scene, indicating that derailed equipment was pulled for some distance in a derailed state before it finally 'went off exploring.'

Once the initial POD is located, the track structure for at least 50–100 m before the POD should be examined in detail for conformance with governmentally required and generally accepted industry standards for track construction and maintenance. In the United States, these minimum requirements can be found in 49 CFR (Code of Federal Regulations) Part 213. Track defects that, depending on their severity, may lead to derailment include

1. broken joint bar between two rails (especially in older rail and at cold temperatures);
2. broken rail (internal defect in steel, especially in older rail and at cold temperatures);
3. excessive cross-level between rails – one rail higher or lower than its adjacent rail can cause car body roll and resulting wheel lift and may also cause harmonic rocking at specific speeds. Commonly caused by poorly tamped rail joints;
4. poor track alignment – 'wavy' track;
5. track gauge (distance between rails) too wide (causes wheelset 'drop-ins') or too narrow (causes wheelset/rail climbovers, rail rollovers);
6. ties deteriorated to the point that they are unable to hold spikes or other fasteners – leading to rail rollovers, particularly the high rail on curves;
7. track switch or turnout to adjacent track not properly adjusted or maintained – 'point gap' between switch point and stock rail – allows incoming wheel flanges to 'pick the point' and derail;
8. insufficient ballast or rail anchoring to support track or to restrain longitudinal movement under load (often resulting in 'heat kinks');
9. insufficient spikes or fasteners to hold the rail in place, allowing rail rollover under load, particularly the high rail on curves; and
10. insufficient rail superelevation on curves for the authorized track speed.

To be considered potentially causal in nature, track defects identified during the postaccident inspection must have existed prederailment, and not have been caused by the derailment.

Another potential cause of a derailment is equipment (rolling stock) failure. Common causes of equipment failure that can lead to derailment include

1. broken wheel – may be caused by defective steel or thermal cracking from brake shoe heating;
2. broken axle – defective steel;
3. roller bearing burn off – lack of lubrication, internal flaws, manufacturing defects. Check data from nearest hot bearing detector for confirmation;
4. rail car truck (or 'bogie') hunting – oscillating back and forth between the two rails as the train progresses, exerting high lateral forces on the rails, most common on straight track with worn rail at 70 kph or higher; and
5. truck (or 'bogie') warp – causes wheelsets to move in a canted fashion relative to the track. This accelerates wear on the track and railcar components, and may cause a wheel-lift derailment if sufficiently pronounced. Present when bogie components are worn and 'out of square' relative to the direction of travel.

The search for an equipment-caused derailment begins at the leading car in the line of derailed cars. Any equipment-related derailment cause will likely be found in this car, but in certain conditions, may be found in the first or second car to the rear of the leading derailed car, but rarely further back than this in the line of derailed cars. Bogies and wheelsets (which are often separated from their respective cars and sometimes partially buried in the ground) should be matched with their corresponding cars, if possible, and examined in detail for any of the above defects. As with track, in order to be considered potentially causal, the defect must have existed prederailment and not have been caused by the derailment. This can often be determined by the presence or absence of corrosion in cracks and fractured steel surfaces of wheels, axles, and bogie components. Freshly cracked or fractured surfaces will not exhibit corrosion on the fractured surfaces. Partial corrosion (corrosion up to a point on the fractured surface) often indicates that the crack existed for some time before it finally sheared completely. The services of a metallurgist should be secured to complete the analysis whenever such evidence is present.

Another potential derailment cause, though much rarer than any we have discussed thus far, may come into play when a train is passing over a turnout (switches trains from one track to another) that is power-operated (as opposed to hand-operated), and controlled remotely by a train dispatcher. Signal track circuitry at the location detects the presence of a train and electrically locks the switch, preventing it from changing position, for the duration of time that the train is

passing over it. If this signal track circuitry fails in some fashion, it may be possible for the power-operated turnout to change position as the train is passing over it, causing a derailment.

Derailments sometimes result from improper train makeup and/or train handling. The placement of a block of heavier cars near or at the rear of a string of empty or lighter cars can produce 'slack run-ins' if the train brakes are not applied with the necessary finesse. The heavier cars will tend to bunch toward the leading end of the train, derailing lighter cars between them and the locomotives. This effect is especially pronounced on curves. A locomotive engineer's failure to control slack action in a long train, particularly in an area of undulating grades, can produce the same effect.

Human Factors Considerations – Level Crossing Accidents

No analysis of level crossing accidents would be complete without consideration of the human factors performance of motorists as they approach crossings. This subset of human factors research has been studied extensively over the past 40 years, culminating in hundreds of research reports, many of which are available on the Internet. As such, the field, as it relates to level crossings, is far too voluminous to cover here in the level of detail that it merits. We can, however, explore some of the high points and whet the reader's appetite for further investigation on the subject.

In general, motorists are imperfect decision-makers, and often underestimate the speed at which trains approach crossings, leading them to attempt movements over the track, which they have insufficient time to complete safely. The perception/reaction time (PRT) required for a motorist to perceive a hazard and begin to take corrective action varies with expectancy. The less expected a hazard is or the more complex the environment from which hazard clues must be drawn, the longer the PRT. In most cases, an assumed PRT of between 1.5 and 2.5 s is typical for level crossing accident reconstruction, unless a more detailed value derived from actual study or reenactment at the subject crossing is available.

The motorist's prior observations of one or more 'false activations' of active warning devices at level crossings (instances in which the active warning devices falsely indicate the approach of a train, indicating that it is not safe to proceed over the crossing when in fact it is) tend to reduce the credibility of crossing warning devices in general, prompting them to attempt passages over crossings in violation of activated flashers and gates. Studies have shown that motorists tend to assign a decreased credibility to activated warning devices at a particular crossing even if their observations of 'false activations' occurred at other crossings.

Frequent false activations of level crossing active warning devices have many potential causes, principal among them being poor maintenance on the part of the railroad company.

Failure to maintain clean, mud-free track ballast (the crushed stone that the track rests on) within the approach to the crossing is the most common cause of false activations. This condition worsens over time, as repeated rail traffic grinds portions of the crushed stone into dust that then combines with water (rain, melted snow and ice, road salt applied over level crossings in winter for the benefit of highway traffic) to form an electrically conductive slurry bridging the two rails. This electrically conductive slurry interferes with the crossing signal equipment's ability to reliably detect approaching trains. The equipment is designed to recognize the onset of this unsafe condition and activate the warning devices continuously until ballast conditions improve (rain stops and ballast dries out) or the equipment is repaired or readjusted by signal maintenance personnel. This unsafe condition is easily preventable by careful and proactive attention to track and crossing signal maintenance.

Motorists often exhibit impatience with activated level crossing warning devices, particularly if they have been held for long periods of time, with or without the passage of a train, by such warning devices in the past. This impatience may prompt them to attempt unsafe maneuvers around activated flashers and lowered gates. The higher the degree of reliability with which the active warning devices at crossings operate, the greater their credibility is and the fewer violations of activated warning devices by motorists that are likely to occur.

Glossary (SWGDE, 2011)

Bit Short for binary digit. Fundamental unit in computing. It has two possible values: 1 or 0.

Bitstream image A bit-stream image is a sector-by-sector/bit-by-bit exact copy of a hard drive or other storage device.

Data Information in analog or digital form that can be transmitted or processed.

Hash or hash value Numerical values, generated by hashing functions, used to substantiate the integrity of digital evidence and/or for inclusion/exclusion comparisons against known value sets.

Hashing function An established mathematical calculation that generates a numerical value based on input data. This numerical value is referred to as the hash or hash value.

Integrity verification The process of confirming that the data presented are complete and unaltered since time of acquisition.

Metadata Data, frequently embedded within a file, that describe a file or directory, which can include the locations where the content is stored, dates and times, application-specific information, and permissions.

Partition User-defined section of electronic media.

Storage media Any object on which data are preserved.

Work copy A copy or duplicate of a recording or data that can be used for subsequent processing and/or analysis.

History/Background

Digital evidence is an emerging area in the field of forensic science. As society becomes more dependent on technology, more of daily lives are reflected in the world of cyberspace. The notion of a carbon footprint has become popular in the media, what is equally as important is the digital footprint. Technologies such as Facebook, Twitter, Google+, and text messaging allow one to record and share almost all facets of daily lives. One has friend-finding applications on GPS-enabled cell phones, security cameras that monitor daily travels, and Internet companies record one's web-browsing activities and predilections. One's health records, phone conversations, and even book- or magazine-reading habits are monitored and recorded. These days most people conduct their banking online, with little or no interaction with the physical bank. The end result of all this is that digital evidence is poised to surpass the volume of physical evidence, such as paper documents or paper receipts.

The term digital evidence is bandied about in the vernacular and often highlighted in movies and the popular media. But what exactly does this term mean? While there are several definitions available, the more common definition of the term is

Digital data that establish that a crime has been committed can provide a link between a crime and its victim, or can provide a link between a crime and the perpetrator.

Like physical evidence, digital evidence exists in a crime scene. To be more accurate, digital evidence exists in two crime scenes, the physical and the cyber or digital realm. An example would be e-mail evidence. This evidence could be stored on a laptop that exists in the physical world, but the actual content of the e-mail is in the digital world. Thus, one

needs to define this second type of crime scene, the digital crime scene. A digital crime scene is defined as

The electronic environment where digital evidence can potentially exist.

Digital evidence falls within the larger category of digital forensic science. Digital forensic science is defined as

The use of scientifically derived and proven methods toward the preservation, collection, validation, identification, analysis, interpretation, documentation, and presentation of digital evidence derived from digital sources for the purpose of facilitating or furthering the reconstruction of events found to be criminal or helping to anticipate unauthorized actions shown to be disruptive to planned operations.

As a field, digital forensics is relatively new to the forensic sciences. The American Academy of Forensic Sciences (AAFS) added a Digital and Multimedia Sciences section in February 2008. Prior to this time, practitioners and scientists engaged in digital forensics belonged to other sections such as the General Section or Engineering Sciences Section.

Apart from the establishment of its own section within the AAFS, digital forensics as a concept first appeared in the 1970s as a result of the efforts of law enforcement in the United States, Canada, and Europe to have laws passed to deal with technology-related crimes. In the 1980s, police agencies in North America and Europe started to create dedicated computer crime units such as the FBI's Computer Analysis Response Team (CART), which led to international conferences in the 1990s designed to begin the work of harmonizing efforts at the international level.

In the late 1990s, the International Organization for Computer Evidence (IOCE, European) and the Scientific Working Group for Digital Evidence (SWGDE, USA) began formal

discussions on standardizing investigative approaches for dealing with digital evidence.

In 2000, the FBI opened their first Regional Cyber Forensics Laboratory (RCFL). The goal of the RCFL program was to provide computer forensic resources to state and local law enforcement. The program has expanded to 16 RCFL's covering the majority of the United States.

In 2003, the American Academy of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) included specific certification criteria for laboratories handling digital evidence. The inclusion of these criteria mirrored the European efforts related to ISO 17025 requirements for international laboratories.

As was previously mentioned, the AAFS in 2008 recognized its first new subsection in over 25 years. The Digital and Multimedia Sciences section is the current home for digital forensics and digital analysis in the context of a forensic science.

Current Context

Evidence that is digital in nature is an integral part of most modern-day investigations (Figure 1). Digital evidence has been used as corroborative evidence in cases that range from homicides to cyber stalking, extortion, and child custody cases. Dennis Rader, the BTK killer, was eventually caught as a result of digital evidence found on a diskette. Investigations relating to intellectual property (IP) or fraud and embezzlement rely more heavily on digital evidence than on document-based evidence. In the business setting, the volume of digital documents has surpassed paper-based documents. The paper documents that exist are commonly printouts of digital or electronic documents.

E-mail-based evidence has been the proverbial 'smoking gun' in numerous high-profile cases such as Enron and the antitrust investigation involving Microsoft. The sheer volume of e-mails produced daily (estimated to be in the billions worldwide) make this kind of evidence common to any investigation. Some federal law enforcement agencies estimate that at least 80% of their current and future investigations involve or will involve digital evidence.

Standards

Given the recent emergence of digital analysis, there are no standards that are recognized as being definitive. Several organizations such as the SWGDE, American Society for Testing and Materials (ASTM), the IOCE, the National Institute of Justice (NIJ), and the Association of Chief Police Officers (ACPO) are developing guidelines and best practices. However, most of these are works in progress and are not intended to be checklists or formal standards at this time.

The development of standards and certifications is further complicated due to the diverse communities that are enveloped by the field of digital forensics and digital evidence analysis. These communities include (1) law enforcement, (2) private sector, (3) government/military, and (4) academia. These communities have subtly different objectives and thus different requirements for practitioners in their area.

Digital Evidence Life Cycle

Similar to other forms of evidence, digital evidence has a life cycle. The digital evidence life cycle parallels the flow from data to information to knowledge. Digital evidence begins its life cycle in the domain of data. Once the data have been located, the context of the investigation as well as the content of the data moves it into the domain of information. This information is then used to make decisions, test hypotheses, or legal theories and to provide opinions – the knowledge realm.

The National Institute for Standards and Technology (NIST) in the United States has developed a diagram that illustrates the progression of the digital evidence life cycle in the context of the Digital Evidence Process Model (Figure 2).

DE Process Model

The digital forensics process model consists of five phases: identification, collection/acquisition, transportation, analysis/examination, and report.

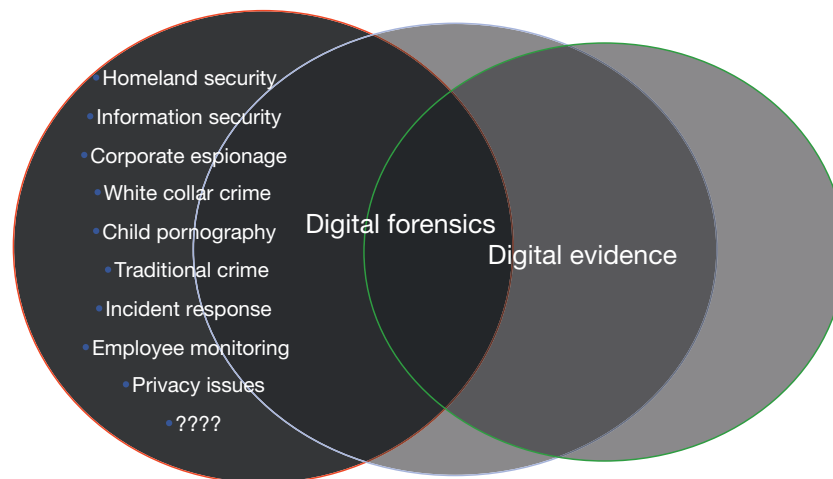

Figure 1 Context of digital evidence.

Figure 2 NIST model.

Identification

Prior to any collection, the evidence or potential evidence must first be identified. Unlike with physical evidence, digital evidence is latent. One cannot see bits and bytes or data flowing through the airways via wireless transmissions. Humans are dependent on technology to assist in abstracting and representing the data in a way that is human readable (e.g., computer monitor displaying the data, directory trees listing files on a hard drive). This latent characteristic of digital evidence makes it difficult to identify and requires that investigators take a very methodical approach.

Investigators commonly look for well-established ‘containers’ of data. These include hard drives, thumb drives, digital versatile discs (DVDs), mobile phones, external USB drives, laptops, etc. Unfortunately, due to the rapid changes in technology, unconventional containers must also be searched for. These can include digital video recorders, MP3 players, and even Internet-connected televisions.

Another factor that complicates the identification phase is that containers of data can have very small form factors such as USB thumb drives or SD memory cards. These devices can be as small as a quarter or a person’s thumbnail and still hold Gigabytes of data. These small devices are easily hidden by someone and are easily destroyed by breaking the connector or the device in half.

Similar to the steps for collecting physical evidence, the entire identification process must be well documented and recorded. The basic foundation for a chain of custody must be established at this phase and maintained throughout the entire process. It is preferable to use a digital video camera and record the crime scene.

Collection/Acquisition

Once digital evidence and/or the containers that contain the data are identified, the data must be acquired in a manner that is consistent with the precepts of the chain of custody and ensures that the evidence will be admissible in a legal proceeding. This usually entails taking steps to ensure that the data are not modified or altered and if changes must be made, to thoroughly document what has been changed. In this phase, there are actually two major considerations: is the device/system still powered on and will remain so – live system or is the device/system powered off and/or could be powered off – dead system or autopsy approach. Devices/systems that are powered

off or can be powered off without disrupting the integrity of the evidence are the easiest to deal with. An example would be a computer system such as laptop or workstation that is powered off.

The standard procedure for powered off systems is to remove the storage device and using a write blocker (preferably a physical or hardware write blocker), create an electronic copy of the drive or device. This electronic copy is referred to as a forensic copy or forensic bitstream image. There are two types of images that can be made, physical copy or a logical copy. A physical copy contains all the data on the storage device, from the very first sector to the last sector. A logical copy only captures the data in the defined volume or partition on the device/hard drive (e.g., the ‘C’ drive on a windows system). If possible, a physical copy is preferable, as it captures all the data and helps to place evidence in the correct context.

The approach for collecting evidence from a live system is more complicated than the autopsy approach. One of the fundamental concepts in forensics is to avoid altering the crime scene or at least keeping any disturbances or changes to a minimum. With live systems, it is necessary to execute some tool on the suspect system in order to make a copy of all the volatile data. Volatile data or evidence here refers to information that is lost when the electrical power is cut to the system. These volatile data can include contents in random access memory (RAM), process tables, connection logs, and network connections. In this situation, an investigator would use a piece of forensic software that is stored on an external device such as USB thumb drive, DVD, or some other externally connected disk. The external device contains all the necessary code to run the application without having to use any of the software resources on the suspect device other than the RAM. Here is where potential problems can occur. When the forensic software is executed, it will use a portion of the RAM on the suspect system, and this will push out or replace whatever data were in the area of the RAM that is now being used by the forensic software. The digital crime scene has now been altered, albeit in a minimal manner. However, despite altering the evidence, the courts have allowed this procedure, as it is the only viable method available at this time. Of course extensive documentation of the process and how it may have impacted the suspect system is required. The forensic software run on the suspect system will collect an image of the RAM, running processes, and other such volatile data.

While the current trend is to have investigators to create an image (block device image) of a physical device, there are certain circumstances where a physical-to-physical-device

acquisition is preferable. To elaborate, in the case of physical-to-physical device acquisitions, there is a direct one-to-one relationship. In these instances, there are advantages and disadvantages. With a physical-to-physical copy, the drive that the image will be copied to must be at least the same storage capacity or larger. For every drive/device that is being copied, there will be a corresponding physical drive for the copy to be stored on. Drive-to-drive copies have the advantage of being very fast, and it is straightforward to determine whether it is an exact copy or not. The determination that the copy is an exact or valid copy is done using hash functions. Hash functions allow one to take an arbitrary-sized data input and produced a fixed sized output, a hash total of the data in our case. In the case of MD5, the output is a hash function represented by 128 bits (Figure 3). The hash function is very sensitive to bit wise changes. This means that if any bit of the data is changed, the resultant 128-bit hash total is completely different.

The use of hash functions to ensure integrity and validity of the forensic copies is not practical with live systems. Since the system is powered on and running, numerous changes and updates are occurring during the imaging process. If the desired image is a physical copy then using hash functions is useless, as the state of system when the original hash total is calculated will be different by the time the forensic copy is made. If a logical image is being acquired on a nonactive volume (not the partition or volume that system was booted from) then using a hash total to compare the image to original is fine, nothing will have changed on the nonactive partition during the time span of the imaging process. If an image is being acquired that included the boot volume on a live system then it is the same situation as with the physical, the state of the system will be changing during the process, making a hash total comparison meaningless.

The common practice is to compute the hashes before the drive is imaged and then calculate the hash of the image and compare the outputs. If the hash totals match, this is sufficient for the copy to be considered an exact duplicate of the original drive. In some jurisdictions, the forensic image or copy qualifies as 'best evidence,' and it can be stipulated that the original is no longer required. This is more common in large organizations that may wish to wipe the drive and repurpose it back into operations.

A second copy of the original can be made. The forensic image is copied, and the subsequent computed hash total of this copy is calculated and compared to the total of the forensic image. If they match then the second copy is considered an exact copy of the original as well. This process can be used to prepare numerous copies of the original if required, without touching the original again.

The original drive or device can be placed in secure storage or as mentioned, wiped, and repurposed. The first copy is deemed the library copy and is used to make further copies if required. The second copy is the working copy and is used in the subsequent stages of the process model.

It should be noted that the acquisition process as described could also include encrypting all the forensic

images. Compressing the image(s) to save on storage space can also be conducted without impacting the integrity or validity of the images.

Transportation

Given the volatile and fragile nature of digital evidence, care must be taken to ensure that evidence is not altered or damaged during the stage of transporting from the scene to the laboratory or more secure environment. Digital evidence is very sensitive to changes in temperature, humidity, and any type of magnetic field, radiofrequency field, or static charge. The common practice is to place devices such as hard drives, thumb drives, and so on into antistatic bags and then place these into shock-resistant and water-resistant containers.

The storage of digital evidence can also be problematic as evidence (e.g., last numbers dialed) on some devices such as mobile phones can be lost if the battery is depleted. Other storage devices such as DVDs must be protected from sunlight or other natural lighting, as this will degrade the compounds used to store the data. Magnetic-based storage hard drives start to decay the minute they are manufactured, so any long-term storage (>5 years) can result in areas of the drive demagnetizing, and the data stored in these areas becomes inaccessible.

Analysis and Examination

The next step in the process is to begin examining the data in order to determine what if anything is of evidentiary value. An analogy for this phase in the process is that of a funnel (Figure 4). Raw data are entered into the large end of the funnel. These data are filtered based on the context of the investigation. Data that are determined to be important (in order to either confirm a legal theory or negate another) become evidence. This evidence is further filtered and interpreted by the analyst until a decision or decisions are made, which are directly supported by the derived evidence.

The extremely large capacity of storage devices (e.g., hard drives) makes it impractical to examine all the data that are contained on the device. Therefore, an examination plan is required. The plan weighs the context and goals of the investigation. Context can refer to the type of the investigation (e.g., threatening e-mails, theft of IP, possession of contraband images).

Figure 4 Examination and analysis.

Understanding this context allows the investigator to develop a decision tree to guide the exploration of the data.

Digital Evidence Artifacts

Since the analysis of the data must be somewhat focused, certain artifacts are routinely examined during the course of the analysis phase. These artifacts include e-mails, web browsing histories, chat and texting logs, deleted files, and timelines. Other secondary artifacts consist of documents, pictures, and spreadsheets.

The sheer volume of e-mails that are sent and received in any given day makes e-mail a target-rich item for investigators. E-mails contain various metadata items such as the IP address of the system sending the e-mail, the IP addresses of all the mail systems it passed through (as well as time stamps), and in some cases, the type of e-mail client used to create the message. These metadata are contained in the header portion of the e-mail that is human readable. However, e-mails can have the source address tampered with to make it look like it came from somewhere or someone else (this is referred to as 'spoofing'), and the header information can be stripped out by anonymous remailers.

The use of graphical web browsers such as Safari, Internet Explorer, and Mozilla has led to the popularity of the Internet. Since web browsing is such a common activity, a detailed history of what sites were visited and when what was downloaded from these sites and what terms were searched for in the common search engines are important sources of evidence. In many cases, the history of search terms (e.g., buying guns, cleaning a crime scene, chloroform) have been vital in the successful prosecution or exoneration of an accused person.

The explosion of social networking and the need to be in constant communication with one's friends and family have resulted in there being an increase in evidence related to texting, chatting, and other social media technologies. Most texting and chat programs have the ability to record a log of the conversation, and many providers for this media store the conversations on their servers. Depending on the case, these records of the communications can provide a link between the suspect and the victim, the suspect and the activity, or in the case of civil disputes and IP cases, the intent of the party in question. In several criminal cases, individuals have bragged about their crimes on their social network pages or texted their accomplices or friends to discuss the criminal activity.

Files and data that have been deleted or placed in the recycle or trash bin on the system are of special interest since these are items that in some cases, a person wants to hide or get rid of (i.e., delete). Modern operating systems (e.g., Windows 7, OS X Lion) and file systems (e.g., NTFS, HFS+) allow for files to be deleted or placed in the trash without actually removing the data from the system. These files still exist but the location in the file system that they occupy is flagged as being available to store new data. Unless and until new data are written to these areas, the deleted files are recoverable.

As with physical investigations, reliable time lines are important in digital evidence analysis. A reliable reconstruction of events and cause-effect relationships can be the difference between a determination of guilt or innocence. Time lines

allow for the examination of alibis and can place an individual at certain critical locations at a particular time (mobile phone evidence is often used for this purpose as most phones log their positions relative to cell towers and wireless telecommunication companies store tower records). Unfortunately, developing a reliable and accurate chronology of events can be difficult with digital evidence. While most modern operating systems and file systems record the time a file was modified, accessed, or created/copied, these timestamps depend on the system's clock and the operating system clock. Users usually have access to their clock/time applications, which they can use to modify their system's time. This modification would alter the time stamps on files and impact their reliability. Even if the system's clock is not tampered with, computer systems do not have accurate clocks. Research has shown that over the course of a day, the system clock can drift anywhere from minutes to hours out of sync with the actual time.

Electronic documents, spreadsheets, and pictures in relation to digital evidence are for the most part identical to their physical counter parts. Most individuals store their documents, spreadsheets, and pictures within default locations as determined by their operating system and file system. Unlike physical copies of documents and spreadsheets, digital versions contain metadata such as version changes, comments, and authorship and time stamps such as creation and modification. An investigator could readily determine when the document in question was created or deleted and who created the original document and could see all the different versions of the document from when it was first created to when it was last modified.

With pictures, digital images can contain information about the type of camera that was used to take the picture and if the camera or device (e.g., mobile phone) has a GPS function, the exact geographical location where the picture was taken at (i.e., geotagging).

Conclusion

Digital evidence investigation and analysis are a relatively new field/activity within the forensic sciences. As the field matures, it will develop a standardization of methods, tools, processes, and certifications as well as a common corpus of knowledge. In its present state, the most that can be said is that the five-step process of identification, collection, analysis, and examination and reporting mirrors the phases used in the other physics-based forensic sciences and are compliant with basic crime scene investigation procedures.

Society's ongoing dependence on technology increases the importance of analyzing digital evidence. Today and into the foreseeable future, individuals live in two realities, the physical and the virtual or cyber. Hence, the need to effectively deal with evidence that is digital in nature is paramount, as this category of evidence surpasses the physical in terms of volume. This field is somewhat unique, as it deals with a man-made science (computers and technology) and not a natural science (e.g., biology and chemistry) as the other forensic sciences do. Technology is constantly changing; therefore, tools, techniques, and processes that worked yesterday may not work tomorrow.

The legal justice system is also less comfortable in dealing with digital evidence than it is in dealing with more traditional scientific evidence (e.g., physical, biological, and chemical). To some, the Internet and technology are still rather magical and therefore, evidence derived from this media is either believed at face value or classified as being suspect and incomprehensible. As the current judiciary ages out and is replaced with a newer generation, this uncertainty and fear will naturally be reduced.

Digital evidence analysis, while representing a different mode of evidence than the physical, still must be held to the same scientific and legal standards as the other forensic sciences.

Investigation and Analysis of Structural Collapses

RT Ratay, Columbia University, New York, NY, USA

DB Peraza, Exponent, Inc., New York, NY, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Beam A relatively long structural member, usually in a horizontal position spanning between supports, carrying loads transverse to its longitudinal axis.

Bracing Providing support against lateral movement.

Buckling Sudden lateral displacement of a slender structural member under axial compressive loading.

Collapse Total failure, falling down.

Column A structural member, usually vertical and in compression, such as a post or pillar.

Formwork A temporary construction to contain the wet concrete in the desired shape while it is hardening.

Fracture surface The surface along which a material breaks.

Lateral-torsional stability Ability to resist buckling which involves lateral deflection and twisting.

Reasonable engineering certainty The term arises from courtroom rules of evidence and, as such, is a legal term. Attained when the investigator satisfies himself/herself of the legitimacy of his/her conclusions, and supports his/her opinion with sound technical foundation.

Serviceability The capability of the structure to perform the function for which it was designed.

Space frame A three-dimensional structural framework, such as a roof structure with structural members in more than one plane.

Stress Internal force per unit area, usually given in pounds per square inch, or kilogram per square centimeter.

Understrength Having strength less than required to resist the loads.

Overview

Structural failures may be defined as the unacceptable difference between intended and actual performance. At one extreme, it may be a 'catastrophic collapse' with fatalities, and at the other extreme, it may be a serviceability issue, such as excessive deflection/displacement or premature cracking.

Most structural failures are the result of human activities. Errors that can result in failure can occur anywhere along the planning–design–construction–service lives of a constructed facility:

In planning – design concept

In design – detailed design, calculations, drafting

In the design–construction interface – shop drawing detailing, drafting, review, and approval

During construction – erection, inspection, accident

In service – misuse, overload, alteration, adjacent construction, lack of maintenance

During demolition – improper methods

Structural failures, whether they occur during construction or during the service lives of structures, are usually followed by forensic investigations. They often create claims of loss that result in legal proceedings toward the resolution of those claims. The determination of the cause of the failure and the parties responsible for it, as well as the technical presentation of the claim on the one hand, and the presentation of the technical defense on the other hand, require the engagement of structural engineering experts.

The investigator of a failure needs to have an understanding not only of structural behavior but also of codes and standards and of the design–construction process in order to recognize where along the process errors were likely to occur that could have precipitated the failure.

The purpose of a collapse investigation is threefold: (1) to determine the cause(s) of the failure, (2) to identify the party (ies) responsible, and (3) to learn from the mistakes.

The typical process of forensic investigation of a failure, hence the activities of the expert consultant investigating the case, may be coarsely outlined as follows:

- First-response and preliminary assessment
- Development of investigation strategy
- Fact-gathering and document review
- Engineering analyses to determine cause(s) and responsibilities
- Reporting

If the failure results in legal action, further investigation may be done as part of overall litigation support, or just in response to the findings of opposing experts.

Except for litigation support, the process is not country dependent. It depends rather on the nature and magnitude of the failure; fatalities, if any; the monetary value of damages and claims; and the time and money available.

Following the 10 October 2002 collapse of a footbridge during construction, shown in [Figure 1](#), it was obvious that the omission of internal lateral-torsional stability in the design, absence of external bracing during construction, and lack of communication between the designer and contractor contributed to the failure. Very little investigation was required to confirm the initial findings. Following the 18 January 1978 collapse of the large space-frame roof structure, shown in [Figure 2](#), under snow load years after its completion, it was clear from preliminary analyses that the primary cause of the failure was an error in the design of the compression members of the space frame, but the engineering investigation of the case continued on for years.

When a collapse occurs, the full scope of work of the investigation can include the following activities:

Figure 1 Marcy Bridge, Utica, NY, USA, collapsed during construction (Courtesy of Robert T. Ratay).

Figure 2 Hartford Civic Center, Hartford, CT, USA, space frame roof collapsed years after construction (from Carper KL (ed.) (1989) *Forensic Engineering*. New York: Elsevier Science).

First steps

Initial field observations

- Engineering assistance in rescue operations, if any
- Assurance of public safety
- Documentation of field conditions
- Preservation of physical evidence
- Interviews of eye witnesses
- Initial engineering assessment

Initial stabilization, repair, and restoration

Main investigation

- Familiarization with the project
- Planning the investigation (document reviews, analyses, tests)
- Identifying additional expertise required
- Site inspection and collection of physical evidence
- Review of design and construction documents

- Establishing the design, construction, and service history
- Formulating possible failure scenarios
- Performing analytical studies and tests
- Evaluating probability of possible failure scenarios
- Selecting most probable failure scenario
- Scrutinizing convergence of evidence
- Demonstrating validity of opinion
- Reporting
 - Interim communications
 - Oral presentations
 - Written reports
 - Presentation materials and exhibits
- Litigation support – if required
 - Depositions
 - Preparation of demonstrative materials
 - Testimony

First Steps

As with any forensic investigation, the first steps in the investigation of a structural collapse must focus on the preservation of highly perishable physical evidence. There are, however, several aspects that are unique to structural investigations.

First of all, structural collapses usually involve large components. These components often can only be handled using construction equipment. In many cases, not only are the components large but they may also be numerous. A large area will often be needed in order to lay out and securely store these components for further inspection and/or testing. This area, due to its size and the need for the use of heavy equipment to handle the components, often is located outdoors. Items that cannot tolerate exposure to the environment may be placed within a secure trailer or protected in some other manner.

And of course, the nature of the perishable evidence is different than it is in other forensic sciences. Following are examples of highly perishable evidence that are associated with structural collapses.

Collapse Configuration

The collapse configuration is a highly perishable evidence. The postcollapse position of the components provides valuable information regarding the sequence of the collapse, which can help identify the area where the collapse originated. It can also provide information regarding the mechanism of collapse.

There are many valid reasons why the physical evidence will need to be moved, modified, or even destroyed. Chief among these is the need to rescue or recover victims who are trapped in the debris. Rescue workers may have to cut structural members and remove debris in order to reach victims. Another reason is the need to prevent further collapse, which could result in additional injuries or property damage. This may require the demolition of certain portions of the structure and/or the installation of shoring or bracing. Finally, there are cost-related reasons, such as minimizing business interruption or the need to complete a construction project by a given date.

It is therefore important to quickly capture the collapse configuration. There are a number of useful techniques for doing this, such as aerial photography, photogrammetry, three-dimensional (3D) laser scanning, and personal observation.

Aerial photographs help provide an overall view of the postcollapse location of components, which can be invaluable. Likewise, overall photographs from various angles and vantage points can provide valuable perspectives.

Software is available to help convert photographs into 3D digital models using the principles of photogrammetry. Digital models created using this technique can be very useful for visualization. Although the dimensional accuracy is variable, it is sufficient for many purposes. The main advantage of this technique is that no special field equipment or personnel is needed, since photographs can be taken with an ordinary camera. In many instances, the technique can be applied 'retroactively' to photographs that were not taken with this technique in mind.

A technique for quickly capturing accurate dimensional information of a large site is the use of 3D laser scanning. This is a powerful technology that is capable of capturing the coordinates of thousands of points per second, over a 360° field of view. Scanners typically have a range of nearly 1000 ft and an accuracy of approximately 1/4 in. The technique involves the use of a tripod-mounted laser scanner and is often performed by firms with expertise in land surveying. The data are postprocessed with specialized software to create a 3D digital model that can be viewed from any angle.

It is important that the engineer investigating a collapse be present while the structure is dismantled. High-quality field notes, photographs, and possibly video are invaluable tools for documenting the collapse configuration and the removal process. In case of large collapses, it will be important to use a nomenclature system for uniquely identifying the various components as they are removed. If drawings for the structure are available, they will provide an obvious starting point for a nomenclature system.

Fracture Surfaces

The fracture surfaces of steel components can contain features that provide clues as to the type of load that caused the failure. These features can be obscured, or altogether destroyed, if the surface is not protected from the elements and is allowed to corrode. A common technique to protect these fracture surfaces from corrosion is to spray-paint them with a pigmented coating. The color provides visual confirmation of which surfaces have been protected. The coating can be readily removed once the item has reached the laboratory to allow study of the surface.

Curing Concrete

If a concrete building collapses during construction, one potential cause that must be investigated is whether the formwork was removed prematurely, before the curing concrete had reached the required compressive strength. It is therefore important to determine, as closely as possible, the strength of the curing concrete at the time of failure. The strength of recently placed concrete can change dramatically in the first few days and weeks of its life, so it is important that this be done as quickly as possible. The most reliable technique for doing so is to locate the standard test cylinders that were cast from the batch of concrete of interest when it was placed and to have these tested immediately, as opposed to waiting 7 or 28 days as is customary.

Snow and Other Loads

When roofs collapse under snow load, it is important to try to quantify the weight of the snow that was on the roof at the moment of collapse. The weight and distribution of the snow will change as it melts, it slides, and/or it is blown by the wind. The most direct and reliable method is to take measurements on the roof itself, using containers of known size and scales. Measurements of the snow weight on nearby roofs and on the ground next to the collapsed roof are also valuable.

If there are other loads that may have played a role, such as heavy construction materials that were stockpiled on a floor that was under construction or items stored in a warehouse, it will be important to estimate their weights and location before they are removed.

The Investigation

Once the perishable evidence has been secured, the focus of the forensic evidence turns to the actual investigation.

Investigations of collapses are usually led by structural engineers. However, depending on the nature of the collapse, additional expertise may be needed to perform a comprehensive investigation. The investigative team may need other types of engineers, scientists, and specialists, such as geotechnical engineers, metallurgical engineers, petrographers, chemists, fire engineers, wood scientists, polymer scientists, and crane engineers. It is important to identify the needed expertise early and to engage the appropriate people.

There are a number of fundamental questions that a structural investigation must address.

What was the trigger of the collapse? Every collapse has a trigger. The trigger is the event that caused the collapse to occur at that particular moment. In many cases, but not all, the trigger is obvious. Triggers fall into one of two broad categories: (1) added load applied to the structure or (2) a reduction in the strength of the structure. Examples of added load may be wind load, weight of freshly fallen snow, placement of heavy construction materials on a floor, and impact from a vehicle. Examples of reduction in strength include the removal of a structural member during renovation, corrosion of steel members, and deterioration of wood members.

What was the status of the construction at the moment of collapse? This is an important question if the structure was being constructed or renovated. In some cases, it takes considerable effort to determine this, since documentation of the progress of construction is often incomplete. A related question is what activities were being performed at that moment? These questions often require the input from eyewitnesses, who may be reluctant to share what they know. Whenever possible, eyewitness statements should be corroborated by physical evidence.

What external loads were acting at the time of the collapse? External loads include environmental loads, such as wind load, snow load, and seismic load. Other external loads include live load and loads such as people, furniture, materials, or vehicles. The self-weight, or dead load, of a structure is also usually considered an external load. Some of these loads, such as dead load, are well defined for a given structure and can be determined relatively accurately. Others, such as the load from an impacting vehicle, cannot be determined as accurately.

What were the internal stresses or forces that were acting? Once the external loads have been estimated, they are converted into internal stresses or forces using the principles of mechanics of materials and of structural analysis. For simple structures, hand calculations may be sufficient. For more complex structures, specialized software is often used to create a digital structural model and to perform the analysis. The structural model includes the geometry of the structure, the mechanical properties of each component, the restraint conditions, and the external loads. The structure can be modeled as a wireframe using 1D elements, as surfaces using 2D finite elements, or as a solid with 3D finite elements. The model may be of an entire building, including columns, beams, and floor slabs, or it may be of a single connection. The geometry may be based on design drawings for the structure, if observations of the as-built structure indicate it was built in substantial accordance with the design. Otherwise, the as-built configuration must be used.

What was the resistance of the structure? The resistance of the structure is determined using principles of structural engineering and mechanics of materials. For example, the buckling strength of a compression member depends on the material strength, the member length, the cross-sectional geometric properties of the member, end restraints, and other factors. Laboratory testing may be needed to determine the actual material strength or the strength of an assembly.

Where did the collapse originate? Most collapse initiate at a singular point, and knowing the origin of the collapse is helpful for determining the sequence and progression of the collapse. The collapse configuration, which was discussed under 'First Steps,' can often provide valuable clues regarding the origin and the sequence. The results of the structural analysis, discussed above, will also help identify the 'weakest links.' There are some cases where the precise origin is immaterial. For example, if a series of roof girders were all constructed with the same defect, and they all collapsed, it may not be important to determine which of the girders failed first.

What was the 'primary cause' of the collapse? This is the deficiency that, by itself, is sufficient to cause the collapse. Another term commonly used, primarily for failures in industrial facilities, is 'root cause.' Examples of primary causes include under-strength material, an omission by the design engineer, failure to construct in accordance with the design, and inadequate inspection. The primary cause is typically determined by synthesizing all the available information: eyewitness accounts, physical evidence, laboratory testing, and results of structural analyses. As with other forensic investigations, the 'process of elimination' plays an important role in determining the primary cause(s). This involves the following:

1. Identify all possible causes.
2. Eliminate those causes that are not probable.
3. Investigate the remaining causes to determine which one(s) best satisfies the physical and engineering evidence.
4. Determine, if possible, the most probable cause to a level of reasonable engineering certainty. In some cases, there may be multiple causes that are highly probable.

What were the contributing factors to the collapse? A contributing factor is one that, by itself, is not sufficient to cause the collapse, but in combination with other factors can cause the collapse to occur at a particular moment. Or, once the

collapse is initiated, a contributing factor can allow the collapse to progress further or more completely than it would have otherwise. Determining these factors also requires evaluating all the available information. It also often requires determining the relative contribution of each of these factors to the collapse, which may require performing multiple hypothetical analyses.

Who was responsible? If there is litigation involved, it may be necessary to go to the next level, which is to assist the attorneys in determining liability. In order to do this, it is necessary to understand the roles and responsibilities of the various parties, to be familiar with the applicable building codes, to be aware of industry practices, and to obtain and meticulously review all the project documents. When opining about responsibility, the investigators have to compare the activities of the various parties to some accepted standards of performance. The performance of engineers is compared to the 'standard of care,' which is defined as "That level or quality of service ordinarily provided by other normally competent practitioners of good standing in that field, when providing similar services with reasonable diligence and best judgment in the same locality at the same time and under similar circumstances." The performance of contractors is usually defined by the 'duty to perform,' that is, strict adherence to plans and specifications.

Several reports of seminal collapse investigations are suggested for further reading at the end of this article. They illustrate the variety of approaches that are used to answer these crucial questions.

The Investigator/Expert

There are several published definitions of the expert investigator/witness. What they all include are that the expert has the knowledge and skill necessary to evaluate the technical aspects of the case, can use that knowledge and skill to conduct the evaluation, can form an opinion with 'reasonable engineering certainty,' should be unbiased and free from conflicts of interest, should be truthful, and, if the case winds up in a court of law, should assist the trier of fact (the judge and the jury) in understanding the technical aspects of the case.

Professional opinion cannot always be with 100% certainty. The courts in the United States, for example, require that the opinion be only 'with reasonable degree of engineering certainty.' The phrase arises from courtroom rules of evidence and, as such, is a legal term. This suggests, among other things, that all mutually exclusive modes of failures need not be investigated if evaluation of the most reasonable causes leads to a definitive conclusion. This may pass the legal test, but might fall short of the definition of a thorough investigation.

Engineers should be thorough in their investigations and careful with the statements of their opinions. A credible, honest, ethical investigator satisfies himself/herself of the legitimacy of his/her conclusions and supports his/her opinion with sound technical foundation.

Often, different investigators arrive at different conclusions. This may be because two engineers working independent of

each other may have access to different data, approach the problem from different directions, put unequal emphases on the same evidence, and/or be influenced by their past experiences, preexisting opinions, and biases.

Experts should be aware that their services can be subject to claims of negligence, and the liability may extend far beyond the fee for services. A client who used an expert may find the basis to sue that expert, if he/she lost the case or believes that the expert did not perform adequately. Simply being an expert on the losing side of a case is not sufficient cause for a client to bring suit against an expert; however, if the expert's performance was below the applicable standard of care, he/she may be held liable for the loss of the case.

Postinvestigation

To the credit of the structural engineering profession, failures have been and continue to be used to improve design and construction practices.

A valuable peripheral benefit of a laborious investigation is a clearer understanding of structural behavior and a better appreciation of pitfalls in the current practices. These can provide information and material to bring about changes in design and/or construction practices, codes, standards, oversight, and regulatory procedures that can prevent reoccurrence of similar collapses.

Biomechanics of Human Gait – Slip and Fall Analysis

TE Lockhart, Virginia Tech, Blacksburg, VA, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Friction demand (μ_d) Friction demand (μ_d) is a ratio between horizontal and vertical ground reaction forces

during the heel contact phase of the gait cycle. It represents the overall requirement for the foot to not slip significantly.

In order to analyze the principles of body stability and the mechanism of slips and falls, it is necessary to understand the dynamic principles of human locomotion. In this article, the biomechanics of human gait is presented to elaborate on the 'human' aspects of slip and fall accidents. This information may provide a comprehensive tool for forensic scientists to better understand the relationship between the 'biomechanics of human gait' and 'slip and fall accidents' and may assist in formulating cogent expert opinions.

Biomechanics of Human Gait

The purpose of this section is to assist in the understanding of the gait mechanisms involved in walking, which reflect the dynamic principles of each body segment in locomotion that are relevant for investigating slip and fall accidents. The purpose is also to describe the motor control strategies associated with walking to reveal the complex aspects of initiating events leading to fall accidents and its relationship to posture and balance in human gait. Understanding the motor control strategies associated with walking may provide us with information relevant to decouple the system into identifiable pieces for the scientific reconstruction of accidents. Here, we begin with some basic concepts in human gait.

Locomotion, an inclusive characteristic of all animals, is defined as the process by which an animal moves itself from one location to another. Walking is characterized as a method of locomotion involving the alternate use of the two legs to provide both support and propulsion. Finally, 'gait' can be described as the mannerism or style of an individual's walking pattern. Human locomotion falls into a general category known as 'striding bipedalism,' a locomotion activity in which the center of gravity is carried alternately over the right and left foot. Normal walking depends on a series of reciprocal movements involving the alternation of the function of each leg between supporting the body and advancing into the next position. These complex tasks are governed by open- and closed-loop motor control systems.

The mechanical definition of human walking and especially the function of gait may help us to better understand human locomotor control. In essence, the main purpose of walking is to transport the body safely and efficiently across the terrain. In order to do so, five major functions of gait must be performed during each step: (1) maintaining upper and lower limb support (such as preventing collapse of the leg during stance phase of the gait cycle), (2) maintaining upright posture

and balance of the body, (3) foot trajectory control (such as acquiring safe ground clearance and heel contact), (4) mechanical energy generation to maintain or increase forward body speed, and (5) mechanical energy absorption to decrease forward speed of the body. All of these major functions must be performed within the biomechanical constraints of the body and the physical constraints of the environment. Additionally, the central nervous system (CNS) must also integrate efferent feedback from sensory organs to generate the correct patterns of moments of force at each joint to compare and represent the internal model against the real-world interactions.

Body Segments in Locomotion

Apart from the multiple variations that may occur between different individuals or within the same individual (for instance, as a result of changes in the speed of walking), there are certain observable events that are shared by all. This is because the mastering of the erect bipedal type of locomotion is a learned process and associated with certain personal peculiarities superimposed on the basic pattern of erect bipedal locomotion. In the following subsections, the process of walking in terms of body segments (i.e., lower and upper extremities) in locomotion is further reviewed.

Lower Extremities: Gait has been studied using the 'walking cycle,' which is the time interval between successive floor contacts of each foot. The activity of one leg can be divided into a short swing phase and a longer stance phase.

The stance phase occurs when the foot is in contact with the floor (starting at heel contact (passive) and ending at toe-off (propulsive)) and the swing phase occurs when the foot is advancing forward to take the next step (Figure 1). During each walking cycle, there are two periods of single-limb support and two brief periods of double-limb support (while one limb is about to begin the swing phase and while the other has just ended the swing phase).

Forward walking is achieved by pushing off the stance leg while swinging the other leg forward. At the time of the heel contact phase of the gait cycle, the forward-moving heel contacts the ground and as the limb is kept relatively straight, deceleration of the foot converts to acceleration of the hip. During this phase, the hip and knee extend. Continued forward motion of the body results in the forefoot coming to the ground, and the propulsive part of the support phase begins. At this phase (the muscles plantar flex the foot, flex the knee, and extend the hip), the heel is raised and pushes the foot

Figure 1 The time dimensions of walking cycle.

backward. This is associated with fixation and elevation of the pelvis by the abductors as well as tilting of the body toward the swing leg that allows it to land in a line anterior to the stance leg. The backward (propulsion) force is resisted by friction under the sole.

During the swing phase, the leg is flexed and slightly rotated externally at the hip, flexed at the knee, and dorsiflexed at the foot. Throughout the remainder of the swing phase, the limbs move under the influence of gravity alone, and finish in a position which allows direct entry into the next step.

Heel Velocity: An important lower extremity variable such as heel velocity during walking provides a linkage between motor control and slip severity as the control of the foot during swing is essentially a ballistic and positional task. Horizontal velocity builds up gradually after heel-off and reaches a maximum velocity late in the swing phase and drops rapidly to near zero just prior to heel contact.

The vertical trajectory during the mid- and late swing phases drops rapidly, but, just before the heel contact event (based upon the stride period), the vertical drop is arrested about 1 cm

above the ground level. During the last 10% of swing, the heel is lowered very gently to the ground as horizontal velocity decreases rapidly to near zero. **Figure 2** shows the body kinematics at HC for a typical trial. It can be seen that the forward velocity of the body's center of gravity was 1.6 m s^{-1} and the heel velocity was reduced to 0.4 m s^{-1} horizontally and a mere 0.05 m s^{-1} vertically.

The significance of the heel velocity before the HC is that at the end of the swing phase, the heel velocity must be reduced sufficiently so that a dangerous slip will not occur. Walking speed influences heel contact velocity, that is, faster walking speed will increase the contact velocity. In order to reduce the forward velocity of the foot prior to heel contact, the foot is slowed through earlier and/or increased activation of the hamstring muscles. These muscles become active at the termination of swing phase by elongating as they act to decelerate the swinging leg (this is a very effective use of muscle). Decelerating the swinging leg at an appropriate time requires attentional resources via sensory modality.

Upper Extremities: Corrective postural movements are made by the upper body, arms, and shoulder. In walking, arm swing is used to offset some of the rhythmical acceleration and deceleration of the trunk by the leg movements, and also to damp out the rotational forces on the trunk. The arm swing varies considerably with variation in the speed of the walk. In the unladen state, the arm swings forward from the shoulder with

Figure 2 Body kinematics at HC for a typical walking trial. Adapted from Winter DA (1991) *Biomechanics and Motor Control of Human Movement*. New York, NY: John Wiley & Sons Inc.

the arms hanging more or less relaxed in a sagittal plane, but may move slightly toward medial plane. In the laden state, however, these dampening effects are not available. Load carrying (in front) also displaces the body center of mass (COM) anteriorly, placing it closer to the forward edge of the supporting base, thus requiring additional rotational torque at the foot–ground contact. Increasing the rotational torque during heel contact phase of the gait may increase the friction demand and increase slip severity. Additionally, blocking the visual path with a load may further influence the awareness of an impending slip perturbation.

Ground Reaction Force

The mechanics and the forces involved in slipping are important in understanding fall accidents. The forces applied by the foot to the floor at the point of foot–floor contact act in three directions: vertical (F_v), horizontal (F_H) in the direction of body motion, and horizontal transverse (F_T) to the direction of body motion. Note that by Newton's third law, the ground reaction forces exerted by the floor on the foot are equal and opposite to the forces exerted by the foot on the floor. During heel contact, there is a resultant forward thrust component of force on the swing foot against the floor. This results in anterior/posterior shearing forces (F_H) acting at the foot–floor interface. Walking speed, which is the product of cadence and step length, affects the magnitude of forward horizontal force (F_H). Forward horizontal force (F_H) increases with increasing step length and cadence; however, the effects of cadence are more pronounced than those of the step length.

Lateral-transverse force (F_T) is the result of the lateral momentum during the gait. This lateral momentum exists due to an out-toeing walking pattern. However, the force component F_T can be ignored in normal level walking due to the relatively small transverse forces compared to the other ground reaction force components observed in locomotion experiments.

Vertical force (F_v) is the result of the body weight and the downward momentum of the swing leg against the ground during heel contact. Vertical force (F_v) is affected by walking speed and cadence, which, as previously stated, has a more pronounced effect than step length.

Required coefficient of friction (RCOF): The required dynamic coefficient of friction (DCOF) represents the minimum (dynamic) coefficient of friction (COF) that must be available at the shoe–floor interface to prevent forward slipping at heel contact. Perkins used a force platform to measure the horizontal (F_H) and vertical (F_v) components of the force exerted between the shoe and the ground during normal walking. An analog divider calculated the ratio of horizontal to vertical forces (F_H/F_v) and displayed this on an oscillograph as a function of time (**Figure 3**).

Perkins found six peak forces in the normal gait cycle. The first four peaks occurred during the landing phase and the remaining two peaks occurred during the takeoff phase. Peaks 1, 3, and 4 are caused by a forward force, whereas peaks 2, 5, and 6 are caused by a backward force on the force platform.

Peak 1 is caused by the force of impact of the heel tip against the force platform and has a forward direction as a result of the approach angle of the heel to the ground.

Figure 3 Gait phases in normal level walking with typical horizontal, vertical, and their ratio for one step. Reproduced from Gronqvist R, Roine J, Jarvinen E, and Korhonen E (1989) An apparatus and a method for determining the slip resistance of shoes and floors by simulation of human foot motions. *Ergonomics* 32(8): 979–995.

However, this peak has been found to be inconsistent due to low vertical force during this phase (peak 1).

Peak 2 is caused by a backward force exerted on the heel of the shoe shortly after contact. This force has been noted by several investigators but no reason for its existence has been suggested.

Peaks 3 and 4 are caused by the main forward force which retards the motion of the body and leg. During peaks 3 and 4, the vertical force has risen and a significant proportion of the body weight is being applied through the heel tip (less than 0.1 s after heel contact). Therefore, the error in F_H/F_V ratio is relatively small. As more of the body weight is progressively transferred to the contacting foot, the center of gravity of the body moves over the now stationary foot and the forward force causing peak 4 decreases. During the takeoff phase, the F_H/F_V

(again) increases due to the force (peaks 5 and 6) exerted by the foot propelling the body forward. The significance of the ratio (F_H/F_V) is that it indicates where in the walking step a slip is most likely to occur. If the magnitude of F_H/F_V exceeds the COF between the two surfaces at a particular moment in time, a slip will occur. In this view, there are two critical gait phases in normal level walking from the viewpoint of slipping: (1) shortly after the heel contact, when only the back edge of the heel is in contact with the ground (peaks 3 and 4 in Figure 3). Peaks 1 and 2 are not considered hazardous because F_V is quite small at peak 1 and because F_H is directed backward at peak 2. (2) At the moment of toe-off, when only the forepart of the shoe is in contact with the ground (peaks 5 and 6 in Figure 3) – here, the required static COF demand is important to thrust the body forward. Theoretically, forward slip at peaks

3 and 4 during landing is more hazardous since the forward momentum of the body will continue to apply the body weight on the slipping foot. Conversely, backward slip at peaks 5 and 6 is less likely to be hazardous, as most of the body weight has been transferred forward from the slipping foot to the opposite leading foot. Backward slip at peak 2 shortly after landing appears to be hazardous, but the likelihood of slip continuing in a backward direction is less as the force rapidly changes direction.

Static Versus Dynamic COF (Tactile)

Tisserand found that rank-order correlation with subjective judgments of slip resistance was negligible for static COF measurements and very high for dynamic COF measurements. Additionally, Harris and Shaw found a high correlation between (walker's) opinions of slipperiness and the kinetic friction of wet floors. Their results are in close agreement with Strandberg and Lanshammar's walking experiments demonstrating that kinetic friction values, measured with sufficient sliding velocity, correlated better with the actual risk of falling than low-speed kinetic friction values or static friction values. Another study by Swensen et al. compared the perceived slipperiness of steel beams by both professional ironworkers and students. They were asked to rate and rank the slipperiness of each beam that was either uncoated or coated with contaminants (water, clay, and oil) after walking across the beams. The results of this study indicated that there is a strong correlation between dynamic COF values and subjective ratings of floor slipperiness. Figure 4 shows the result of a series of experiments using ten subjects and five different shoes. The mean subjective ranking and the ranking using the dynamic COF are very similar.

Visual Versus Tactile Sensation

Cohen and Cohen further explored the perceptual and cognitive factors involved in the perception of floor tile surface slipperiness. The results of this study also demonstrated that

tactile cues are most sensitive to physical measurement of dynamic COF. A follow-up field study of the psychophysical assessment of the perceived slipperiness of floor tile surfaces concluded that people tended to make predictions about the slipperiness of walking surfaces and verified these expectations as they crossed them. The results suggest that visual cues to slipperiness are inferior to tactile sensation. They also suggested that in real-world conditions, the perception of walking surface slipperiness is probably the result of tactile cues, with visual impressions being confirmatory. Thus, in unfamiliar conditions, people may rely on the primary but inferior visual information about a surface's traction until they actually walk on it. The potential for an accident can be created due to misjudgment of slipperiness based on initial visual sensing and the limited time available to make immediate adjustments in gait to accommodate for the hazardous condition.

Slip Resistance Measuring Devices

Many devices have been developed by individuals, organizations, and federal agencies (e.g., OSHA, NIOSH, and NBS) to quantify the slip resistance of floor surfaces (i.e., COF). At least 70 different meters have been cited in the literature; however, none of these devices are universally accepted. In general, most devices fall into three categories: drag/towed-sled, pendulum, and articulated strut types.

There are two approaches to measuring friction. In the direct approach, the test device measures or indicates the horizontal and vertical forces. These include drag-type meters and articulated strut devices. The indirect approach calculates the frictional force by observing an energy loss in the test device. The most common example of the indirect approach is a pendulum-type device. These devices are limited in their ability to simulate biomechanical factors for an accurate DCOF measurement.

Strandberg and Lanshammar stated that on the basis of tribology and biomechanical analysis of slips and falls, the slip-resistance meter should reproduce the following operating variables from crucial gait phases: (a) contact time and normal

Figure 4 Comparison of mean subjective ranking by ten subjects and ranking using static and dynamic COF for five shoes. Subjective binary choice test. Reproduced from Tisserand M (1985) Progress in the prevention of falls caused by slipping. *Ergonomics* 28(7): 1027–1042.

force time derivative, for the influence of surface patterning and its drainage capability; (b) foot angle, for testing the most critical part of the shoe; (c) contact force application point at the shoe; (d) vertical force, for correct pressure in the contact area; and (e) sliding velocity, for correct dynamic friction forces.

The versatility of different meters has been compared and commented on by many investigators. Due to its heavy weight and bulkiness, the James Machine can be used only in a controlled laboratory situation for testing sample floor material, not the actual floor. The NBS-Brungraber Tester, on the other hand, is easier to handle and can be considered as a portable James Machine. The Tortus provides a permanent trace record when connected to a chart recorder, whereas most devices provide only a visual reading of the peak COF (analogy meter or gauge). However, drag-type devices have overcome most limitations and generally met with the greatest acceptance among both researchers and practitioners. The BOT 3000 digital tribometer can also provide both static and dynamic COF measures.

Trajectory of the Total Body Center of Gravity

The body's center of gravity is a key factor in human gait analysis as it reflects the motion of the whole body. The center of gravity is the theoretical point about which the mass of that body is evenly distributed. Reduction of the partial body masses into a common center of gravity or mass simplifies the movement dynamics to a point where the effect of the moving forces upon the mechanism of gait as a whole can be deduced. In the human body, the location of this theoretical point will depend upon several factors including the distribution of segmental masses and the location of those segments.

In the standing position, the center of gravity is situated centrally in the pelvis, approximately at the level of the second sacral vertebra. However, during forward walking, the equilibrium is lost with the takeoff of the propelling foot when the body's center of gravity momentarily lies beyond the anterior border of the supporting surface, and regained as soon as the swinging leg is extended forward and the heel touches the

ground. Additionally, the legs move forward and backward relative to the trunk (torso), the arms swing, and the trunk moves up and down and from side to side during locomotion. Consequently, the center of gravity progresses forward and at the same time moves up and down and from side to side.

In normal level walking, the center of gravity describes a smooth sinusoidal curve when projected on the plane of progression (Figure 4). The path curve of the common center of gravity in the sagittal plane moves up and down. This motion is sinusoidal, with a period of approximately 50 mm in extent for adult males at normal walking speed. The summits occur at the middle of the stance phase of each side and the lowest points occur during double support when both feet are on the ground (Figure 5). At the peak of vertical movement, the horizontal velocity reaches a minimum (maximum acceleration). Conversely, the reverse is true at the time of lowest trajectory. The magnitude of the vertical excursion during free-cadence walking correlated significantly with the length of the stride and the peak-to-peak vertical oscillation increased as cadence increased.

In the frontal plane, the common center of gravity moves from left to right as each leg alternately becomes weight bearing. It follows a smooth sinusoidal curve, but with only one oscillation per stride as opposed to the two vertical oscillations in the sagittal plane (Figure 6). The center of gravity attains its greatest distance from the midline shortly after the support of the standing leg is shifted to the whole sole. At this point, there is an inversion of motion (the velocity is zero and the acceleration is maximal). Afterward, the center of gravity follows the period of double support and the velocity increases as the center of gravity again approaches the midline.

Shimba and MacKinnon reported that the lateral path of the center of gravity passes forward along the medial border of the foot (sometimes slightly outside that border: ± 2 cm; Figure 7). The lateral movements represent automatic postural adjustments, shifting the line of gravity alternately toward the eccentrically placed bases of support in keeping with the demands of stability.

In the transverse plane, the center of gravity carries out forward and backward movements (U shape). In this plane,

Figure 5 The path curve of the common center of gravity in the sagittal plane.

Figure 6 The path of the common center of gravity in the frontal plane.

Figure 7 Lateral pathway of center of gravity passing forward along the medial border of the foot. Reproduced from MacKinnon CM (1990) *Control of Whole Body Balance and Posture in the Frontal Plane During Human Walking*. University of Waterloo.

the center of gravity moves forward commensurably with the movements of the pelvis. The maximum forward point is reached as the heel is set to the ground and the maximum

backward movement occurs at the takeoff phase of the gait. The amplitude of these backward and forward oscillations is about 12 mm.

Balancing the Center of Gravity of the Human Body

Achievement of even sinusoidal displacements depends on smoothly coordinated angular displacements of the various segments of the lower limb. Various investigators used a series of simple models to illustrate how this smooth sinusoidal displacement pathway is achieved in bipedal locomotion. They show that this type of locomotion requires that the center of gravity be elevated to a height equal to the center of gravity in the standing position. Thus, it will result in a severe jolt at the point of intersection of each two arcs where there is an abrupt change in the direction of movement of the center of gravity. As such, decreasing the total elevation, depressing the center of gravity, and smoothing the series of interrupted arcs require coordinated movements involving all the joints of the lower extremities.

The balance of the human body or its parts requires that all gravitational forces be completely neutralized by counterforces. These counterforces are supplied by the resistance of the supporting surface of the body. However, when gravitational forces fall outside of the supporting surfaces, the translatory force of gravity is not neutralized. In order to neutralize the rotatory forces, the line of COG must also fall in the supporting surface. In general, two factors influence stability: (1) the broader the supporting area (area over which one object is supported by another; in the standing position, the base of support of the human body is the area bounded by the contact points of the feet with the floor) the greater is the force necessary to destroy the balance by throwing the line of COG beyond the supporting surface and (2) the lower the center of gravity is located, the greater is the arc that an unbalancing force must describe before it can bring the center to fall outside the supporting area (i.e., more stable). In the human body, the constant mass is supported in standing on a small base.

Additionally, the area of the base and the position of the center of gravity are subject to constant and rapid changes and, therefore, require a complex reflex system involving the integration of sensory nerves and the motor nerves controlling the muscles to maintain balance in any given posture of the body. The deviation of the center of gravity is constantly monitored by

1. Sensory mechanoreceptors in the capsules and ligaments of joints, which provide information about their position and rate of movement.
2. Stretch receptors in muscles (muscle spindles), which give information on the amount and rate of muscle stretching.
3. Pressure receptors (exteroceptors) in the skin, which provide information about the amount of pressure on the skin of the soles of the feet.
4. The vestibular apparatus, including the semicircular canals found in the inner ear within the temporal bone of the skull, gives information of the motion of the head in all planes.
5. The visual system giving information about the position of the body in relation to objects and surfaces that can be seen.

All this information is processed in the CNS (principally in the cerebellum and the brainstem) and signals are sent to skeletal muscles to contract appropriately to adjust the position of the body to maintain the center of gravity over the base. This process involves unconscious prediction of body motion so that the adjustments are not merely responding to the existing body position, but arranging that the center of gravity to base relationship is appropriate for subsequent movements (i.e., the next step in walking).

Balance Task of Walking versus Standing: Human bipedal locomotion (walking) provides a challenging balance task to the CNS and appears to be completely different from the balance task during standing. During standing, the CNS is challenged to keep the body's center of gravity safely within the borders of the two feet (or one foot if balancing on one foot). Studies of balance and posture during quiet or perturbed standing have identified the ankle muscles (plantarflexors/dorsiflexors and invertors/evertors) as dominant. However, during locomotion, ankle muscles are no longer important because the balance task has changed. As explained in the last section (Lateral Oscillations of the COG), the lateral path of the center of gravity passes forward along the medial border of the foot (even slightly outside that border). Thus, during single support, the body is in a continuous state of falling down because the its

center of gravity is outside the foot. The only way that recovery is achieved is to position the swing limb so that during double support the CNS can make any rebalancing adjustments.

Gait Model: This recovery is a challenging balance task that requires a complex interplay of neural and motor control mechanisms. Motor control is directly linked to the CNS's processing of sensory inputs (vision, vestibular, and proprioceptive systems). The brain constructs internal representations of the world by integrating information from the different sensory systems. In other words, the transformation from sensory signals to motor commands is processed within the CNS. The motor system transforms neural information into physical energy by transmitted commands from the brain stem and spinal cord to skeletal muscles. A system model that mimics the behavior of a natural process is known as an internal model, an important theoretical concept in motor control. The internal models include two main components: inverse model and forward model. An inverse model functions as a motor command computation to calculate the desired states. A forward model acts as a predictor to estimate the next state (e.g., future position and velocity). The sensory systems send inputs to an online controller to make an adjustment in real time. In essence, we use the inverse model to modify our walking behavior; that is, walking off the sidewalk to cross the street and stepping back onto the curb requires online controller. Additionally, the internal model is used to predict, and adapt to, the next step (i.e., forward model); thus, we are able feel momentum changes, for example, when walking onto a broken escalator. The importance of understanding the gait model above is to provide a better understanding of the processes associated with slips and falls. Here, it is clear that 'EXPECTANCY' is required to walk – that is, during walking, we expect the ground to be stable and, as such, we modify our gait to traverse the terrain with appropriate force and speed to safely ambulate; however, if the ground is not stable, there will be a motion perturbation (i.e., expectancy and reality did not match). This perturbation, if not controlled, could lead to slips and falls.

Gait Characteristics Influencing Slip Initiation, Detection, and Recovery

The process of slips and falls can be categorized into four levels as shown in Figure 8. The environmental phase considers the effects of contamination. As noted by Chaffin et al., 'any fluid

Figure 8 The process of initiation, detection, and recovery of inadvertent slips and falls with possible causes and effects. Reproduced from Lockhart TE, Woldstad J, and Smith J (2003) Effects of age-related gait changes on the biomechanics of slips and falls. *Ergonomics* 46(12): 1136–1160.

contaminant between two sliding surfaces will provide lubrication and thereby lower the DCOF values.’ Therefore, the presence of contamination (oil, water, etc.) will reduce the available DCOF of the floor surfaces. In terms of slip-induced falls, friction demand characteristics between the shoe sole surface and the floor surface has been implicated as an important predictor variable related to severity of falls. It was stated that most of slip-induced falls occurred when the frictional force (F_{μ}) opposing the direction of foot movement is less than the horizontal shear force (F_h) of the foot immediately after the heel contact on the floor. The RCOF is defined as the ratio of horizontal ground reaction force to vertical ground reaction force. It represents the minimum RCOF between the shoe and floor interface to prevent slipping. Consequently, slip is initiated by the combination of lower DCOF and higher RCOF. A static COF of 0.5 on a level walking surface has been commonly recommended by standard organizations and by individual authors. Dangerous forward slips that lead to falls are most likely to occur 70–120 ms after the heel contacts the ground.

The sensorimotor degradation in older adults often leads to altered gait characteristics affecting the slip-initiation process. Lockhart et al. reported that older adults’ heel velocity was faster than their younger counterparts at the heel contact phase of gait cycle. Increases in heel velocity during critical weight transfer may increase the potential of a slip-induced fall if the floor is slippery. In addition, the friction demand of older adults was found to be higher than their younger counterparts. It has also been suggested that whole body COM velocity relative to the base of support may be a factor related to RCOF. Slower whole body COM velocity and COM transitional acceleration (velocity changes from heel contact to shortly after heel contact) were reported in older adults. Alterations in these factors can increase the risk of slip initiation.

During the detection and recovery phases of the slip and fall process, the CNS control plays an important role. The CNS must undertake certain processing stages (detection phase) if a fall is to be avoided or compensated for (recovery phase). During the detection phase, a trigger must be sent through the sensory feedback to the motor control regions of the CNS. This process may be initiated by one or more of the following sensory inputs: somatosensors, vision, and vestibular function. At the input stage, any disruption in the quality of the input signal may increase the likelihood of slips and falls. The somatosensors are responsible for proprioception, the sensing of joint and limb motion. The vestibular organs located at the inner ear (semicircular canals and otoliths) detect angular velocity of the head and act as linear accelerometers. Visual cues provide information about the position and motion of the head with respect to surroundings. In the case of posture control, the relevant signals are processed by motion detection circuitry not only in the retina but also in the visual cortex. These sensory signals are fed back to a series of hierarchical feedback loops to generate motor commands.

The reactive recovery phase involves bringing the body COM within stability limits quickly after a slip is initiated. This is achieved through changes in various kinematic, kinetic, and muscle coactivity mechanisms. One of the important mechanisms during reactive recovery is to reduce the displacement of the slipping foot through increased coactivity of the

muscles of the lower extremity. Electromyography (EMG) recorded from the lower extremity showed an increased co-activation of the rectus femoris and hamstrings, along with the tibialis anterior and gastrocnemius muscles, while recovering from a slip. The postural responses generated by distal perturbed leg muscles are of short latencies (65–110 ms), significant magnitude (2–3 times higher than normal walking), and long duration (≈ 150 ms). Numerous studies have linked slower muscle activation rates in older adults as an indicator of increased risk to slip-induced falls. Kim et al. found a decreased hamstring activation rate in older adults and related it to higher risks of slip-induced falls. The postural activity of bilateral leg and thigh muscles and the coordination between the two lower extremities were found to be key to reactive recovery balance control.

An Example of an Expert Witness Report

In this section, opinions and basis for expert opinions will be further described using an example of a case involving a slip and fall accident. First, a general description of the accident is presented – usually, gathered information at this time is in the form of ‘depositions’ from various individuals involved either directly or indirectly in the accident. In addition to witness statements and/or discussions with the potential client, experts also inspect the area (either via photograph, video, or a visit to the accident site) in question and make measurements (e.g., COF, slope, and illumination).

Afterward, the opinion of the expert is presented using a variety of supporting materials linking human locomotor control and fall accidents. Here, we start with a general understanding of the accident at the time of a group’s arrival at a restaurant.

General understanding of the accident

On the afternoon of 26 October 2012, Mrs. AC visited the C’s restaurant in Parkins, Texas, for a lunch after a salon visit with a church group. Mrs. AC and the church group members arrived at the restaurant in a van. It was raining steadily and heavily at the time of their arrival (to the restaurant). As such, the van was parked close to the entrance to accommodate for the rain. Mr. Priggs (Assistant Manager of the C’s at that time) held the front door open as they were entering the restaurant. The first group of ladies entered the restaurant. When Cynthia (a member of the group who witnessed Mrs. AC’s fall from the posterior view) and Mrs. AC entered the restaurant, they were among the last of the group to enter the restaurant.

Mrs. AC entered the restaurant and walked toward the end of the mat to look for the group. She located the group by identifying the ‘backs of their heads.’ She walked from the end of the last mat onto the exposed tile floor, where she slipped and fell to the left side of her body fracturing her pelvis. Mrs. AC was assisted by the restaurant employees until the ambulance transported her to the hospital.

Opinion

The exposed tile floor surface between the ‘mat’ and the carpeted surface of the dining area at the C’s restaurant at Parkins, TX, created an unreasonable hazard and risk of harm to pedestrians.

In order to maintain dynamic balance during locomotor activities and to help avoid slip-induced falls, gait parameters are adjusted to correct for contaminated or slippery conditions. In other words, when confronted with impending slip and fall situations, our walking style (i.e., the gait parameters) is adjusted accordingly to avoid slipping (note: online controller at work). Persons who have a prior knowledge of a contaminated walkway adjust their gait by reducing friction demand characteristics – for example, reducing heel contact velocity and step length by modifying the support leg's muscle stiffness. For younger individuals, this adaptation is quicker (within one step) than for older adults (at least two steps) – that is, it will take them at least one to two steps to adjust their gait to traverse even readily recognizable slippery floor surfaces. Mrs. AC is an older adult.

As indicated, the support leg is modified in muscle stiffness according to the walking conditions to progress the whole body smoothly without abrupt transition of friction demand. The ability to modify the muscle stiffness characteristic of our supporting leg (i.e., make rapid and adaptive adjustment of gait from walking on a nonslippery floor surface to a slippery floor surface) depends upon the quality of the user's perception of the surrounding environment. Hale and Glendon and Tisserand supported that a cognitive process occurs prior to action (locomotor activities) in order to safely traverse over slippery floor surfaces (i.e., online controller). The process starts with expectation – expecting the contaminant (i.e., water, grease, etc.) on the walkway, the area is surveyed (scanned) visually with appropriate thoroughness related to one's expectations. As such, the lack of obvious visual cues to elicit expectation can influence detection of slippery floor surfaces and modification of adaptive locomotor responses.

Furthermore, tactile cues to elicit expectation can also be important. Tisserand suggested that frictional values are estimated and memorized unconsciously from preceding steps (one's own model of slipperiness) and this information is updated whenever the subject feels the floor conditions are different from expected (reality) (note: adaptive controller). In the author's opinion, the cues necessary to correctly detect the prevailing slippery condition were neither obvious nor effective and resulted in a slip and fall accident. In other words, there were no obvious and effective cues to inform Mrs. AC that the exposed tile floor surface between the 'mat' and the carpeted surface was dangerously slippery and as a result Mrs. AC did not adjust her gait to compensate for the slippery floor surface.

Mrs. AC's expectation was influenced by several factors. Any visual cue that may distract a pedestrian's attention away from the slippery floor surface could be potentially dangerous. In this case, visual cues to distinguish the slippery floor surface were not available.

Furthermore, the assumption that the floor will be dry in the area where the fall occurred is lacking support. For example, in the case of heavy pedestrian traffic and heavy rain, water will accumulate on the mat and proceeding steps can track moisture onto the exposed tile floor surface making the floor surface very slippery. (Using a slip meter, the available (relevant) COF can be measured.) This statement is further supported by one of the witnesses to the accident – "The way I

looked at it, the way that it even looked like this, I could see the skid [moisture trail] on the floor like her heel had hit instead of like the flatness of her foot." This statement further corroborates that not only was the tile floor surface wet, but Mrs. AC's gait was also not adjusted accordingly to walk on the slippery floor surface – that is, the usual gait characteristic associated with walking on a slippery floor surface is toe-heel gait to modify friction demand (more vertical ground reaction force than horizontal ground reaction force – as in walking on icy surfaces). In the author's opinion, effective tactile cues necessary for gait adjustment were also lacking.

As indicated above, tactile cues are important in eliciting protective response (i.e., gait adjustments) to walk on slippery floor surfaces. Frictional values are estimated, evaluated unconsciously from preceding steps, and updated readily to traverse the area safely. Walking on a slip-resistant mat first and then stepping onto a slippery surface may create a misperception leading to fall accidents. In other words, the slip-resistant mats provided a secure surface condition for normal walking with no need to modify gait (i.e., heel-toe gait) to traverse safely for Mrs. AC; however, when walking on a slippery surface with secure gait, her heel slipped, and she fell.

In summary, visual and tactile cues necessary to correctly detect the prevailing slippery condition (at the exposed tile floor surface between the 'mat' and the carpeted dining area) were not obvious and created an unreasonable hazard and risk of harm to Mrs. AC. In the author's opinion, the cues necessary to correctly detect the prevailing slippery condition were neither obvious nor effective and resulted in a slip and fall accident.

There are a number of measures that the C's restaurant could have taken to increase pedestrian expectation of slippery floor surfaces and/or reduce the likelihood of falls. One solution would have been to extend the mats covering the tile floor surface all the way to the carpeted area. This would have permitted Mrs. AC to get to the dining area without walking on the slippery tile floor surface. Warning signs such as 'Watch Your Step' and 'Caution – Wet Floor,' which are industry standards for hazardous floors, could have been posted (although warnings can be important, proper mats are the preferred safety measure). More probably than not, these measures would have prevented Mrs. AC's fall and injuries.

C's restaurant failed to institute reasonable measures to reduce the likelihood of falls and breached its duty to maintain its premises in a reasonably safe condition for patrons such as Mrs. AC.

In summary, although biomechanical aspects of gait and posture have been discussed in detail in this chapter, applicable codes and standards should also be referenced. As in all forensic investigations, careful and thorough investigations and analyses must be performed before scientifically credible expert opinions can be rendered.

Forensic Chemical Engineering Investigation and Analysis

DD Perlmutter, University of Pennsylvania, Philadelphia, PA, USA

Introduction

Chemists and chemical engineers are often asked by attorneys to offer scientific and/or technical assistance on matters in controversy when the details involve damage to persons or property from chemicals, fires, or explosions. In addition, if the subjects under examination reach into the court systems, plaintiff or defense arguments may call for expert opinions to support or to refute some position.

Because it is recognized that chemical engineers play an essential role in the design and operation of every chemical and petroleum process, they are often called upon in the aftermath of an industrial accident to evaluate the equipment and practices that were used before and during the event. Their expertise is also sought when fires or chemical events occur in homes or other residential settings. The procedures of evaluation have much in common, but of course, they must be tailored to the details of the equipment being used. In the factory or chemical plant, it will be necessary to examine any mixers, reactor vessels, distillation columns, or separators of various kinds, whereas in a residence, the focus will be on rooms, appliances, and any chemicals in use. In the best modern installations, safety considerations will already have been put in place, but sources of ignition or sources of contamination will still need to be identified.

Huge quantities of natural gas and petroleum liquids are moved every day between refineries and residences through pipelines that crisscross every state and most of the big cities in the United States. Usually the pipelines are buried, emerging only when it is necessary to cross some barrier or for servicing or pumping to the next station en route. Some of the piping is quite old and, occasionally, the welds or seals are inadequate to hold pressure. If leaks are not identified and corrected early, there is a high risk of fire and/or explosion of flammable material. Some very dramatic fires occurred as recently as 2010 in Philadelphia and Texas; the latter event caused one death and eight reported injuries. Chemical engineers are appropriate experts for any investigation of the causes of such events. The 2010 gas release and explosion from the BP Deepwater Horizon rig offshore in the Gulf of Mexico was in the news for months because it was very costly in terms of lives and property, and potentially more damaging to marine life. Eleven men died and many were injured in that event.

There are tens of thousands of chemicals in commerce around the world, and each case is potentially unique in some respect; however, there are some classes of substances and some features of accidents that occur often enough to provide recognizable patterns. With the objective of providing an overview of the wide range of approaches to presenting cases, this article identifies some of the important subclasses and their characteristics and offers examples typical of each one.

In each case being considered, it is essential not only to identify a potentially offending substance but also to consider the

pathways and combinations that produce the hazard by the nature of their interactions. This means, in effect, that all the pertinent science and technology must be factored into the responses. Depending on the specifics, this may call for basic science such as chemistry, physics, or biology; transport properties for heat, mass, or momentum; or design and operations such as are central to any manufacturing process.

Many times an expert will need to find an acceptable and respected standard of practice by which to judge whether a particular device or decision is appropriate for a given circumstance. For such cases, the American Society for Testing Materials (ASTM) has published a series of indexed volumes that may easily be found in libraries or over the Internet. When fires and/or explosions are under examination, the references of The National Fire Protection Association (NFPA) provide standards and codes of behavior to be followed by experts. The Environmental Protection Agency (EPA) provides information on what is allowed in air and water and the Consumer Product Safety Commission is a source of listed hazards in their area of responsibility. Data on chemicals and their properties as well as on thermal and transport properties, heats of reaction, and chemical equilibria are listed in reference handbooks. The forensic expert will find all these useful to evaluate the crucial events in various circumstances.

More detailed discussions of these different matters are divided in this article under the general headings of Fires and Explosions; Pollution and Toxic Substances; and Unexpected Hazards and Unexpected Consequences. Specific examples may also be found in the author's website (www.chemexpertwitness.com.)

Fires and Explosions

In examining the causal chain that might lead to a fire, one must seek not only the flammable substance but also the source of oxygen (or other oxidizing agent) and the source of ignition, be it a spark, a torch, a pilot light, or a cigarette. The flammable material can be in solid, liquid, or gaseous form. Under extraordinary circumstances, it is also possible to get a flame without an external ignition source, but only at an elevated temperature. This *autoignition* temperature is different for each substance. Some examples are shown in Table 1.

If an explosion is under study, it may have been caused by some well-known agents such as nitroglycerine or trinitrotoluene, but it may also have occurred as the result of oxidation of a more common flammable material, if there was some barrier that contained the chemically reacting substances long enough for a pressure wave to violently rupture the barrier. Moreover, not every explosion is the immediate effect of a chemical reaction; it may be caused, for example, by a pressure buildup attributable to gas accumulation in a weak or weakened containment vessel. It is the bursting of the container

Table 1 Selected autoignition temperatures (in °C)

Substance	Autoignition temperature (°C)
Acetaldehyde	175
Acetonitrile	524
Acetylene	305
Ammonia	651
Benzene	560
Carbon disulfide	90
Cyclohexanol	300
Decane	210
Diesel fuel	210
Dimethyl sulfoxide	215
Ethanol	365
Ethylene	490
Methane	580
Nitromethane	379
Pentane	260
Propane	480
Propylene	458

that qualifies as an *explosion*. If the movement within the combustion zone propagates at a velocity greater than the speed of sound in the vapor mixture, it is referred to as a *detonation*.

Flammability Limits

Typically, combustion occurs after a volatile gas or liquid has evaporated sufficiently to produce a flammable mixture in the air. In evaluating such a process, it is most important to take account of the *lower and upper flammability limits* (abbreviated as LFL and UFL). At concentrations below the LFL, there is not enough fuel in the mix to sustain a flame, and at concentrations in the air that are above the UFL, the supply of oxygen in the air is insufficient.

Because the mix is not flammable if either the LFL or the UFL limits are exceeded, fuel concentrations too low or too high as the case may be, it is possible to take advantage of this characteristic by controlled cleaning or by dilution. Before releasing a flammable mixture to the air or to contact with an ignition source, it can be cleaned by passing it through a scrubber, or it can be diluted with nitrogen or some other nonflammable gas.

An alternative description of the hazardous concentration range is sometimes expressed in terms of a *lower explosive limit* (LEL) and an *upper explosive limit* (UEL). This terminology is more precise if the mixture being considered is especially close in composition to the stoichiometric ratio of the fuel to the oxidizer, but as a practical matter, the two definitions are ordinarily treated as identical. It should be noted that organic dust clouds can also have the LEL and UEL characteristics, but the range of sensitivity depends more on particle size than on particular chemical composition.

As shown in **Table 2**, the LFL and UFL values vary over a very wide range, depending on the specific components involved; however, it should be noted that many common hydrocarbons can burn in air only if they are present to an extent between approximately 1 and 7 vol%. The tabulated values are for room temperature and atmospheric pressure, but the limits also depend on temperature and pressure. The flammability

Table 2 Selected values of flammability limits

Substances	LFL Vol% in air	UFL Vol% in air
Acetaldehyde	4	57
Acetyl chloride	7	19
Acetylene	3	82
Ammonia	15	28
Benzene	1	8
Carbon disulfide	1	50
Cyclohexanol	1	9
Decane	1	5
Diesel fuel	1	8
Dioxane	2	22
Ethanol	3	19
Ethylene glycol	3	22
Methyl acetate	3	16
Nitromethane	7	22
Octane	1	7
Propyl acetate	2	8
Propylene	2	11
Toluene	1	7
p-Xylene	1	6

Table 3 Selected values of flash points (°C)

Substance	Flash point (°C)
Acetaldehyde	−39
Acetonitrile	2
Acetylene	−18
Ammonia	11
Benzene	−11
Carbon disulfide	−30
Cyclohexanol	68
Decane	46.1
Diesel fuel	>62
Dimethyl sulfide	−49
Ethanol	12.8
Ethylene glycol	111
Methyl acetate	−10
Nitromethane	35
Octane	13
Propyl acetate	13
Propylene	−108

range widens with increasing temperature, but both the lower and higher values increase with pressure.

Flash Points

Another measure of the degree of flammability of a substance is its *flash point*, a temperature defined by a standardized empirical test. By following a procedure set down by the ASTM, a liquid is heated in a specified manner from below in either a closed or an open cup with an ignition source above. As the liquid heats, it volatilizes, and when the vapor mix with the air is sufficient to ignite, the temperature of the liquid is said to be at its flash point. As with other measures of flammability, the flash point is different for each substance tested. Some typical values are given in **Table 3**. The NFPA Standard 704 has

assigned flammability ratings to liquids, depending on their flash points, as follows:

Rating 0: Substance will not burn.

Rating 1: Flash point equal to or greater than 200 °F.

Rating 2: Flash point between 100 and 200 °F.

Rating 3: Flash point between 73 and 100 °F.

Rating 4: Flash point less than 73 °F.

Pollution and Toxic Substances

If the subject of investigation is the release of a toxic material, it must be asked how the chemical entity was released. Did a vessel leak? Did some container crack, break, or explode? Was the release accidental or intentional for some reason? Where did the substance go and by what path? Some leaks are to the air, some to the ground, some into water tables, or to other above-ground water courses. Finally, what injury resulted from the events and their consequences?

Air Pollution

Toxic ingredients can enter the air from a variety of possible sources. Some are intentionally released if it is believed that the emission is harmless when it is diluted in the air to a low enough concentration. The Clean Air Act, which empowers the EPA, was last amended in 1990, but standards of acceptability change over time, almost always in the direction of more restrictive expectations. This is easily seen when one reviews the limitations summarized in Table 4. The allowable ozone level in city air, for example, has been reduced in the decade between 1997 and 2008 from 0.080 to 0.075 ppm. A new rule proposed in 2011 would require power plants to reduce emissions of mercury by 91% within the next 5 years. More recently, controversy has arisen also on whether the EPA can and should restrict greenhouse gas emissions, especially carbon dioxide.

Some changes in standards can also come about by responses from industry or consents unforced by governmental regulation. By international agreement, for example, the venting of chlorofluorocarbons was phased out to protect the

Table 4 National ambient air quality standards

Pollutant	Primary standards		Notes on
	Level	Averaging time	Averaging time
Carbon monoxide	9 ppm (10 mg m ⁻³)	8-h	Not to be exceeded once per year
	35 ppm (40 mg m ⁻³)	1-h	
Lead	0.15 µg m ⁻³	Rolling 3-month average	Final rule signed 15 October 2008
		Quarterly average	
Nitrogen dioxide	1.5 µg m ⁻³	Annual (arithmetic average)	To attain this standard, the 3-year average of the 98th percentile of the daily maximum 1-h average at each monitor within an area must not exceed 100 ppb (effective 22 January 2010)
	53 ppb	1-h	
	100 ppb		Not to be exceeded more than once per year on average over 3 years
Particulate matter (PM ₁₀)	150 µg m ⁻³	24-h	To attain this standard, the 3-year average of the weighted annual mean PM _{2.5} concentrations from single or multiple community-oriented monitors must not exceed 15.0 µg m ⁻³
Particulate matter (PM _{2.5})	15.0 µg m ⁻³	Annual (arithmetic average)	
	35 µg m ⁻³	24-h	To attain this standard, the 3-year average of the 98th percentile of 24-h concentrations at each population-oriented monitor within an area must not exceed 35 µg m ⁻³ (effective 17 December 2006)
Ozone	0.075 ppm (2008 std)	8-h	To attain these standards, the 3-year average of the fourth-highest daily maximum 8-h average ozone concentrations measured at each monitor within an area over each year must not exceed the given limit (effective 27 May 2008)
	0.08 ppm (1997 std)	8-h	To attain these standards, the 3-year average of the fourth-highest daily maximum 8-h average ozone concentrations measured at each monitor within an area over each year must not exceed the given limit (effective 27 May 2008)
	0.12 ppm	1-h	The standard is attained when the expected number of days per calendar year with maximum hourly average concentrations above 0.12 ppm is ≤1
Sulfur dioxide	0.03 ppm	Annual (arithmetic average)	24-h not to be exceeded once per year
	0.14 ppm	24-h	
	75 ppb	1-h	Final rule signed 2 June 2010. To attain this standard, the 3-year average of the 99th percentile of the daily maximum 1-h average at each monitor within an area must not exceed 75 ppb

The EPA Office of Air Quality Planning and Standards has set national standards for six 'criteria' pollutants. The units of measure are parts per million (ppm) by volume, parts per billion (ppb) by volume, milligrams per cubic meter of air (mg m⁻³), and micrograms per cubic meter of air (µg m⁻³).

stratospheric ozone layer. This transition required substitution for the chemicals used in refrigerants and foaming agents, among other applications.

Sometimes obnoxious material is released from a chemical operation not because it is thought safe, but rather because the hazard is even greater if the toxic material is not released. This is the case, for example, if the buildup of pressure within a vessel would lead to a catastrophic explosion. A safety blow-off valve could then relieve the internal pressure by venting gas to the atmosphere. Most recently, after the huge earthquake and tsunami that damaged so much of the construction in Japan, the operators of a threatened nuclear power plant attempted to flood the reactor with sea water and vented radioactive steam in order to prevent an even worse meltdown within the reactor.

In any of the aforementioned cases, the wind in the region and the natural diffusion from higher concentrations to lower levels spread the toxins and the associated risks. Given information on the amount dispersed and the local conditions, an expert will be able to estimate the potential damage at various distances from the place of the release, allowing parties in controversy to better assess their positions.

Another class of air standards that applies in the workplace is set forth by the Occupational Safety and Health Administration (OSHA). In order to protect workers from lead poisoning, for example, OSHA has set a *Permissible Exposure Limit* of lead in workplace air at $50 \mu\text{g m}^{-3}$ averaged over an 8-h workday for workers in general industry. In addition, the standard specifies the frequency and extent of medical monitoring, and other responsibilities of the employer. If controversy arises, a Chemical Engineering expert could provide information on fumes produced in the process as well as on air monitoring and possible engineering controls.

Ground and/or Water Pollution

When offending chemicals are freed from containment, they can also pass directly into the ground. This is especially noticeable if buried tanks are corroded by long exposure, whatever the setting. Fuel tanks in gas stations are frequently seen being replaced or removed entirely, and the same is sometimes also part of an agreement governing the sale of a home that has buried oil storage. Some industrial operations that need the disposal of unwanted by-products store the waste in an artificial lagoon, that is, in a lake created for the purpose by building confining dams of earth or concrete. With time, these dams can also leak. If they do, the hazardous stored material enters the ground or stream or river in the vicinity. An expert in chemical hydrology can be called upon to estimate effects on the underground water table or on the moving stream above ground.

Storage of Hazardous Materials

Many chemicals are held in storage in anticipation of later use, either as intermediates for further chemical reaction or simply as inventory for later sale. Often, the materials being stored are toxic to humans and animals and, sometimes, they are solvents or diluents that are flammable. When this is the case, special care is needed in providing vessels that will not leak or be corroded by the materials being held in them, but when

these precautions prove to be inadequate, the results are catastrophic.

One of the best known serious examples of leaked material occurred in 1984 at a Union Carbide facility in Bhopal, India, when a storage vessel holding methyl isocyanate released its contents. The chemical was being stored as an intermediate in pesticide manufacture. It is a highly toxic gas and its release killed and seriously injured thousands of nearby residents. Accusations of negligence led to both civil and criminal cases in India, ending in fines and sentences of imprisonment. Improved design and practice now call for smaller inventories of toxins, backup safety procedures, and greater removal from population centers.

Unrecognized Hazards and Unexpected Consequences

A trained eye will sometimes recognize a hazard that is not recognized by an untrained user. Consider, for example, the following instances.

Fire in a Closed Room

It is common practice in construction and renovation to finish a new floor or other wooden surface by coating it with a protective finish such as polyurethane. These finishes are typically applied as a solution or suspension in a flammable hydrocarbon solvent. Upon completion of all or part of the task, the work is allowed to 'dry,' that is, the diluent solvent is allowed to evaporate in order to leave behind the finished protective surface. When the task is completed at the end of a working day, it is commonly convenient to leave the working surface unattended in order that the drying will occur overnight.

If, as is often the case, the room or house being worked on is closed and locked for the night, there is ample time for the evaporating solvent to fill the air in the room to a level that is above the lower flammable limit, creating an accident that is waiting to happen. All that is missing in such a case is a source of ignition, perhaps a pilot light left burning, or a sparking thermostat.

Fire in an Empty Container

When a container holding a flammable liquid is emptied of its contents, it is not truly empty. In fact, it is filled with the air that replaced the withdrawn liquid and with any vapors that evaporated from the liquid. When the liquid is especially volatile, the vapor concentration in the trapped air can exceed the LEL. The mixture will be harmless unless an ignition source is introduced, but this final element would be present if a torch is used to disassemble or clean the vessel.

Spontaneous Combustion

Many chemical substances liberate heat if they are allowed to oxidize in air. Usually this process occurs slowly enough that the heat escapes to the surrounding air, no visible flames are seen, and the process is harmless. Sometimes, however, the

heat is trapped before it can escape. This can happen, for example, if the layer of labile substance is deep in comparison to the path of heat escape, or if the oxidizing chemical is held in a closed container.

In such circumstances, when the heat cannot escape quickly enough, the internal temperature rises. At the higher temperature, the oxidation reaction speeds up, liberating more heat even faster than before. The temperature rises still higher and this feedback snow-balling effect can run away and out of control. Eventually, this process leads to a fire, so-called spontaneous combustion, as the autoignition temperature is reached.

Charcoals and supermarket chars are commonly found to be vulnerable to such fires, especially if they are in closed or insulated containers or closets. Such materials are quite porous and can oxidize in air even when left uncovered in garden centers. Oily rags used to clean up paint spills or to wipe down greasy griddles are similarly in danger of what appears as a spontaneous fire. The recent emphasis on low trans-fat oils in restaurant and fast food cooking has exacerbated this hazard, because chemically unsaturated oils are especially easy to oxidize. Even commercial quick laundering may not sufficiently remove the offending substances from the flammable rags. In such a case, the detergents being used may be supplemented by added enzymatic agents.

Flammable or Toxic Solids

It was noted earlier that volatile materials, those that exhibit large vapor pressures under room conditions, are especially higher risks for fires because their evaporation makes them more likely to create concentrations in the air that exceed the LFL. Most often, these materials are liquids, but it should be noted that some solids, such as naphthalene or mothballs (para-dichlorobenzene), also show elevated vapor pressures at moderate temperatures and are correspondingly hazardous. An expert is able to make a quantitative estimate of the vapor composition.

An Explosive Pharmaceutical

Because chemical agents are used in such a wide variety of applications, the intended use in a particular application may obscure some secondary hazard. In some medical treatments, for example, nitroglycerine in small doses is a pharmaceutical taken by mouth or applied to the skin in the form of a patch. If it is stored in larger quantities, however, it is an unstable hazardous explosive. It was only after Nobel found that nitroglycerine could be stabilized by diluting it in a solid mixture that it could be used commercially as dynamite.

Contamination of Food in Shipment

Much of the world's food is shipped to market over great distances in the holds of freighters. To prevent spoilage, the storage spaces are usually temperature and humidity controlled by the circulation of conditioned air. A unique hazard arises when the ship is fueled, because the vapors of a volatile liquid fuel can enter the circulating air stream and

contaminate the food being carried. Careful assessment of both risks and prevention techniques are called for.

Corrosive and Reactive Chemicals

Among the myriad substances that circulate in modern commerce, there are some that are immediately recognized as being corrosive to common metals as well as to people. These include all the concentrated acids (such as sulfuric, nitric, hydrochloric, and acetic), alkalis (such as lye – caustic soda and ammonium hydroxide), and gases (such as chlorine). These are all corrosives that can attack and chemically destroy exposed body tissues. They begin to cause damage as soon as they touch the skin, eyes, respiratory tract, or digestive tract. The more concentrated the corrosive material is and the longer it touches the body, the worse the injuries will be. When these materials are present in a workplace, everyone who works with them or near them must be made aware of their hazards and how to deal safely with them. A fully prepared Material Safety Data Sheet is essential information and will be asked for by an expert.

In fact, the list of reactive materials is much longer if one recognizes that significant chemical reactions can occur between many pairs of substances, including some materials that are commonly thought of as inert. Plastics can be changed in their properties by exposure to some solvents or alcohols, causing crazing, cracking, or softening, for example. Even some so-called noble metals (gold, silver, and copper) will react with thiocyanides to form soluble compounds. In each case, the result depends on the pair in question, as well as the conditions of temperature, pressure, and concentration, and an expert may be needed to make the essential distinctions.

Epilog

As a conclusion to this article, it is essential to add a caveat, because no single individual can be equally expert in all areas of any field. The forensic chemical engineer must assess any given assignment in the light of his personal skills and specialized knowledge, and be prepared to recuse himself if the matters at hand are not part of his repertoire.

The chemical engineer's skill is most effective when it is applied in direct conjunction with an attorney's view of legal constraints. An example may serve to illustrate the point. Most forensic matters that come to chemical engineers are related to civil suits, focusing on property damage or personal injury. Such cases are either settled out of court or adjudicated with monetary results. On occasion, however, a question arises that has implications for a criminal case. One such matter was raised when instructions posted on the Internet were followed by a teenager who constructed and set off a homemade 'bomb' via the chemical reaction of aluminum foil with an acidic toilet cleaner.

The punishment for this teen's behavior depended on whether or not the device he put together should properly be classified as 'an explosive device' and an expert was called on to testify on this issue. The resolution was based on the detailed understanding of the chemistry and physics involved, but it was the collaboration with the attorney in the case that brought out the distinctions on which the chemical engineering expert based his responses. In forensic matters, it should always be

remembered that each profession enhances the contribution of the other.

Materials Analysis and Failure Analysis

AD Micheals, San Jose State University, San Francisco, CA, USA

The Role of Materials Analysis in Determining Causation of Failure

Materials analysis techniques are key tools in the arsenal of the materials failure analyst. Materials analysis seeks to characterize the intrinsic properties of a material in order to understand the extrinsic properties of the material, that is, how the material should behave in a given context. These intrinsic properties include morphology, composition, crystal structure, atomic bonding, elemental distribution, or, indeed, any characteristic that affects the extrinsic properties of the material. Of these, analysis of morphology and composition frequently provides information critical to failure analysis.

Why did a failure occur? This is the fundamental question to be answered by engineering failure analysis. By understanding and quantifying a failed material's properties, and comparing those values with either the specified properties or an exemplar, the materials analyst can gain an understanding of the role the material played in the failure, whether primary, or secondary to another primary failure.

Materials analysis may help the failure analyst determine:

- When a material failed in relation to a sequence of events. Did it fail and cause an event, or did it fail as a result of the event?
- If design or manufacturing was a factor.
- If the choice of material was a factor.
- Whether inadequate maintenance was a factor.

This article focuses on a selection of important materials failure analysis techniques used to determine morphology and composition (Table 1). Selected applications are presented; a list of useful materials analysis references, including sources for analysis protocols, is provided for further background.

Techniques for Determining Morphology

The characteristics of a material that pertain to its form are collectively termed morphology. Morphology may describe both the external and internal structure of a material. The general external form, including the shape, surface features, and surface texture, as well as the segregation of elements into different regions or phases, and even the internal arrangement of atoms, are important to materials analysis because the structure of a material is intimately related to its properties. The most common morphological characterization technique is microscopy. Various types of microscopies are available. Each technique has different strengths and limitations; therefore, the appropriate method must be selected depending on the information required and the feature size to be observed. The two microscopy techniques covered here are optical and scanning electron microscopy.

Microscopy in Materials Analysis

With the techniques of microscopy, external structure can be magnified and examined using light or electrons. The choice of imaging technique is based on the material being examined, the feature size, and the information desired.

Optical Microscopy

In the analysis of materials failures, information about the root cause may be obtained from visual examination. This is especially true when a fracture surface is available. However, magnification is frequently needed to observe the pertinent features of a fracture surface, the surface morphology, or the distribution and morphology of different phases.

In optical microscopy, examination is done using light incident on the specimen, and reflected back into the eye of the investigator, or to a camera. Transmitted light may also be used with appropriately thin or transparent materials. Traditionally, the light used is in the visible spectrum; however, infrared or ultraviolet light frequencies may also be used, in conjunction with appropriate detectors and equipment to display images in a viewable format.

Because of the limitations of their resolving power, the typical magnification range of optical microscopy runs from 1 to 400 times the original size; 1000 times is the upper limit of the magnification range for conventional optical microscopes. When viewing fracture surfaces, which are typically rough, the depth of field, which is the ability of the microscope to keep the entire field of view in focus, is frequently a limiting factor. Depth of field is a function of the optics of the microscope and magnification (depth of field decreases with increasing magnification), as well as of the behavior of light in general.

Optical microscopy is typically performed with physical glass lenses. In common usage, a single-lens microscope is called a 'magnifying glass,' while 'microscope' refers to a compound microscope. Compared to the single-lens microscope, the compound microscope uses multiple lenses along the optical path to achieve a range of specific magnifications as well as improved magnification and optical quality. A compound microscope suitable for viewing solid specimens is shown in Figure 1.

In materials analysis, there are two specific configurations of optical microscope that are commonly used: the inverted microscope (Figure 2) and the stereomicroscope (Figure 3). The inverted microscope is used to image flat, polished specimens. The specimen is placed above the magnifying lenses, in an inverted position. Because the specimen is flat, the limited depth of field is not an issue; magnifications of 1000 times can be achieved with clear focus in the plane of the specimen. An appropriately prepared specimen can evidence transitions between different phases, dislocation motion, history of heat

treating and mechanical deformation, processing defects, voids, and material composition.

The stereomicroscope consists of two distinct compound microscopes, with offset optical paths terminating at separate eyepieces. The distinct images displayed in the two eyepieces allow for perception of depth. Because the depth of field is inversely related to magnification, magnification is typically limited to 100 times, for the sake of a larger working distance and maintaining an adequate depth of field. Stereomicroscopes are useful for viewing large areas of fracture surface and specimens with large height differences. Stereomicroscopy may often be used to distinguish between various types of fracture, for example, ductile versus brittle fracture, overload fracture, and fatigue fracture.

Samples were polished to 0.05 μm alumina abrasive, and then etched for 10 s with 2% Nital etchant (2% nitric acid in ethanol). The micrographs were taken with an inverted microscope at 400 times magnification.

Specimen Preparation for Microstructural Examination

When analyzing a materials failure, it may be of interest to examine the internal microstructure. Microstructure arises from the segregation of different elements or impurities into different regions; these regions form different structures, called phases, within the material. These phases and their relative, spatial configurations have a significant effect on the properties (both desirable and undesirable) of the material. Many of these structures can be observed and identified with an optical or electron microscope. Specimen preparation procedures have been developed to prepare material specimens for examination of their microstructure. The specimen preparation techniques are collectively grouped under the term metallography. Further information can be found in the References section.

Analysis of failed structural steel using optical microscopy

1040 steel in a structural application failed unexpectedly. The failed steel as well as two 1040 steel samples subjected to different heat treatments were prepared for microscopic examination by being polished and chemically etched. The differences brought about by the heat treatments are visible at the relatively low magnification of 400 times. **Figure 4(a)** shows large grains typical of slow cooling, where time at temperature allows the atoms to move to low-stress positions on the crystal lattice. **Figure 4(b)**, quenched and tempered at a relatively low temperature, is little changed from the fine grain structure typical of martensitic steel; the temperature was too low for the atoms to move and form stress-free grains. The slow cooled sample will have a much lower strength than the quenched sample.

On comparing the failed steel, **Figure 4(c)**, to the samples with known history, it was found that the failed steel had not been strengthened by the appropriate heat treatment.

Scanning Electron Microscopy

For greater magnification, and improved depth of field, an electron microscope can be used. The scanning electron microscope (SEM) is a common instrument, which provides images that are intuitive and easy to understand. Magnification ranges from approximately 20 times to over 20 000 times. Depth of field depends on magnification, but can be as much as 10 mm at low magnification.

Figure 5 Cross-sectional schematic of the column of a scanning electron microscope. Reprinted from Goldstein J, Newbury D, Joy D, et al. (2003) *Scanning Electron Microscopy and X-Ray Analysis*, p. 23. New York: Springer. Copyright 2003 by Springer Science + Business Media, with kind permission from Springer Science + Business Media B.V.

Whereas an optical microscope illuminates the entire specimen at the same time, and creates an image by focusing the reflected or transmitted light, an SEM image is formed by focusing the electrons used to illuminate the specimen onto a very small area and moving (scanning) the focused beam across the specimen's surface. The 'brightness' of the energy reflected as each small area of the specimen is illuminated is measured and displayed as the brightness of a pixel on an image.

A schematic of an SEM is shown in **Figure 5**. Electrons are created by heating a filament (tungsten or lanthanum hexaboride), and are then accelerated by an applied voltage of up to 30 kV. The electron beam is focused by electromagnetic lenses to bombard the specimen surface. The beam of these primary electrons (PE) is scanned across the surface of the specimen.

As the beam is scanned, some of those electrons are reflected after scattering, and other additional electrons may be emitted from the specimen. PEs reflected from the specimen are referred to as backscattered electrons (BSEs). BSEs have relatively high energy, up to that of the incident beam. If a PE interacts with a specimen atom, and transfers some of its energy to that atom's electrons, one or more of the atom's electrons may be emitted as secondary electrons (SEs). SEs are low-energy electrons and are distinguished from BSEs as having less than 50 eV of kinetic energy.

Specialized detectors are used to sense the electron signals. The detected electron intensity is converted into an electrical signal that is displayed as a gray scale image where brightness is proportional to the detected electron intensity. The image is sent to a computer, to be displayed, printed, or saved in a digital format. Magnification occurs when the primary electron beam is scanned across a small area of a specimen, and the image of the scanned surface region is displayed on a larger computer screen.

The imaging process usually takes place under high vacuum, around 10^{-6} torr. The vacuum prevents the PE beam from losing its energy in collisions with gaseous atoms, and allows the emitted signal to reach the detectors.

The resolution of the SEM, while theoretically limited by the wavelength of the primary electrons, is more practically dependent on two factors: the incident beam diameter, or spot size, and the region of the specimen that the primary electrons interact with, called the interaction volume (Figure 6). The beam diameter is determined by how tightly focused the electron beam is. It is controlled by focusing electromagnetic lenses, and can be adjusted from microns to nanometers. The dimensions of the interaction volume depend strongly on the incident electron energy. The width and depth may range from hundreds of nanometers up to approximately $5\text{ }\mu\text{m}$. While a high-energy means that the electrons have a shorter wavelength, the electrons in the beam also have high speed and momentum, which drives the electrons farther into the material. The interaction volume also depends on the atomic number Z of the specimen. As Z increases, the number of outer shell electrons in the atom increases and the incident electrons are

more strongly repelled by Columbic interaction with the atomic electric field. So, for small Z , as with carbon, the interaction volume is large; for large Z , as with lead, the interaction volume is small.

As can be seen from the interaction volume, SEs are most representative of the specimen surface, while BSEs result from bulk interactions. Therefore, for best resolution of surface features, imaging is typically derived from SEs. For contrast differences derived from elemental composition, the BSE signal is typically used.

Analysis of a ductile iron pipe failure with scanning electron microscopy

A ductile iron pipe failed unexpectedly during a pressure test. Samples from the failed pipe and from a pipe that had survived the pressure test were examined in the SEM. Both specimens were prepared by grinding and polishing to a flat surface. The specimens were chemically etched to create a slight but observable height difference between the iron and carbon phases. In this image, the primary contrast is from the BSE signal. The incident electrons penetrate the low Z carbides, with little BSE emission. The higher Z iron phase reflects more electrons, emitting a higher-intensity signal. Therefore, the iron regions appear bright compared to the carbides.

Ductile iron microstructure typically consists of an iron matrix with distributed spherical carbides. The spherical carbides intercept any cracks in the iron matrix and prevent them from propagating. Figure 7(a), the 'good' pipe, shows the expected ductile iron microstructure. Figure 7(b), the failed pipe, shows poorly formed, nonspherical carbides. As a result, the material of Figure 7(b) had a lower-than-expected strength compared to that of Figure 7(a). Additional analysis determined the cause of the poor carbide morphology to be errors in the material composition.

Techniques for Determining Composition

Along with morphology, composition plays an inseparable role in the behavior of a material. While the major elements

Figure 6 The interaction volume is the three-dimensional portion of the specimen that the primary electrons travel through. Its size varies with the kinetic energy of the primary electrons, and with the atomic number of the specimen.

Figure 7 Scanning electron micrographs of two ductile iron specimens. (a) Shows the expected microstructure of the iron matrix with dark spherical carbides; (b) contains poorly formed carbides, which caused lowered material strength.

present in a material obviously affect its macroscopic properties, small amounts may also have a strong effect on properties. An arguably important example of this is carbon steel. Changing the steel carbon content from 0.1% carbon to 0.2% carbon, along with appropriate heat treatment, can increase the tensile strength by orders of 10–100; hardness will increase as well.

The compositional techniques discussed here are x-ray spectroscopy, absorption spectroscopy, mass spectrometry, and thermal and thermogravimetric analysis.

The Physics of Spectroscopy

Phenomena arising from the electronic structure of an atom, and specifically from the arrangements of the electron levels and interactions between them, are unique for each element, and may be used to distinguish the elements present in a specimen. Spectroscopy is the method of detecting the wavelengths of radiation emitted or absorbed by a material and analyzing the results to determine the composition of a specimen. Spectroscopy techniques may determine the types of atoms present, their relative amounts, the type of atomic or molecular bonding, and the ionization state, if any.

Our normal perception of color is a form of spectroscopy that informs us of the composition of what we are viewing, albeit in a limited fashion. While the basis for spectroscopy is rooted in quantum mechanics, it was first described by Newton as he looked at the spectra of the light from the sun separated by a prism. For the purposes of this discussion, however, the shell model of the atom is sufficient to explain the phenomena used in the materials analysis techniques presented.

In the shell model of the atom, a nucleus is surrounded by electrons in specific shells, or orbitals. Each orbital corresponds to a particular energy state. When an inner-shell electron is removed from the atom, the atom is perturbed from its normal state, where all inner shells of the atom are filled. In an attempt to return to the normal, or ground, state, an electron from an outer shell will move to the inner vacant electron position. This position, closer to the nucleus, is a lower energy position; to make the transition, the electron must give up energy. While excess energy can be removed through increased atomic vibration, the electron can also emit electromagnetic radiation

Figure 8 Excitation and relaxation of an atom; excess energy in this case is given off as an x-ray and an Auger electron. Adapted from Goldstein J, Newbury D, Joy D, et al. (2003) *Scanning Electron Microscopy and X-Ray Analysis*, p. 23. New York: Springer. Copyright 2003 by Springer Science + Business Media, with kind permission from Springer Science + Business Media B.V.

(visible light, UV, IR, or x-ray), or transfer a portion of its energy to another electron (Figure 8).

By the quantization of energy theory developed by Planck, the distance between electron energy levels in an atom depends on its atomic number Z , where Z is the number of protons in the nucleus. As Z increases with increasing nuclear charge, the distance between energy levels changes proportionately. For each element, therefore, the energy, or frequency, of the emitted radiation is specific to that element. By detecting and measuring the emitted radiation energy/wavelength, the atomic number can be determined.

The spectroscopic techniques below exploit the relationship between atomic number and emitted radiation frequency to determine composition. To create the emitted radiation, the inner shell electron is removed by a transfer of kinetic energy from an incident particle (a high-energy, high-momentum electron), or from incoming electromagnetic radiation. The method of exciting the emitted signal and the nature of the emitted signal are the primary differences in the techniques.

x-Ray Spectroscopy

When an inner shell electron is stimulated and ejected, and an outer shell electron drops down to fill the hole, an x-ray is emitted. This x-ray is called a characteristic x-ray; it has an energy specific to the element from which it was emitted, and to the specific levels transitioned by the electron.

Two techniques are used to detect the emitted x-rays: energy-dispersive x-ray spectroscopy (EDS) and wavelength-dispersive x-ray spectroscopy (WDS).

There are multiple techniques for stimulating the x-ray emission. In x-ray fluoroscopy, x-rays are used to stimulate

x-ray emission. An electron may also be emitted along with an x-ray; this electron is called an Auger electron, and it can also be used to determine element composition. A useful side effect of the electron beam used in electron microscope systems is the stimulation of x-ray emissions. Hence, EDS and WDS detectors are frequently used with electron microscopes.

Each of these techniques has different detection limits and spatial resolution (Table 2), which arise from the different incoming and emitted signals exploited by each.

Energy-dispersive x-ray spectroscopy

In EDS, the x-ray photon from the specimen impacts a detector, which may be a lithium-doped silicon semiconductor or a silicon drift detector. An amount of charge proportional to the energy of the x-ray is created in the detector (3.8 eV creates one electron in a silicon–lithium detector). This current is converted to a voltage proportional to the initial x-ray energy. The output spectrum is a histogram displaying the number of x-rays detected with respect to energy (Figure 9).

Table 2 Detection limits and spatial resolution for x-ray spectroscopy techniques

Technique	Elements detected	Detection limit (ppm)	Minimum spatial resolution	
			Lateral	Depth
Energy-dispersive spectroscopy				
Wavelength-dispersive spectroscopy	Atomic number > 4 (beryllium and higher)	1000 (EDS), 10 (WDS)	1 μm	1 μm
x-Ray fluoroscopy			10 μm	10 to 100 mm
Auger electron spectroscopy	Atomic number > 3 (lithium and higher)	1000	0.02 μm	0.003 μm

Figure 9 The EDS spectrum of a zinc antimonide semiconductor device.

Wavelength-dispersive x-ray spectroscopy

In WDS, the wave nature of the x-ray is exploited to determine the wavelength. A single crystal, with known atomic plane spacing d , is used as a diffraction grating. An x-ray incident upon the crystal will diffract when it meets conditions set forth by Bragg. When the diffraction crystal is rotated with respect to the specimen, the angle of incidence of the x-ray changes, along with the wavelength needed for diffraction. In this way, a specific range of wavelengths can be scanned and differentiated. Often crystals with different d -spacings are used as needed, depending on the wavelength range to be detected and the sensitivity required. Once x-rays of a given wavelength are being passed by the diffraction crystal, they are counted in a gas proportional counter. The incoming x-ray ionizes the gas in the detector; the resultant free electrons are detected as a current. The current is converted to a voltage; the output is a histogram with number of x-rays versus either wavelength or the corresponding energy.

Choosing between EDS and WDS

EDS measures the energy of the x-ray photon; WDS determines the wavelength of the x-ray. Because the energy of an electromagnetic wave is inversely related to its energy, according to Planck's law, this difference is trivial. The more relevant difference is in the way that each looks at a spectrum. EDS looks across a broad range of energies in the spectrum, while WDS looks at specific regions within the spectrum. With an unknown sample, EDS is more efficient; where the concentration of specific, known elements is desired, WDS is more efficient.

Both EDS and WDS can be accessories to electron microscopes. WDS are primarily found on specialized electron microscopes called electron probe microanalyzers, which are designed to collect very accurate compositional data. Electron microprobe configurations are available with limited or full SEM functionality.

While WDS is slower than EDS for large energy ranges, over a short energy range covered by a single crystal, the total scanning time is reduced. Additionally, WDS detectors have a higher throughput than EDS detectors; so WDS can collect more x-rays than EDS in the same amount of time.

Both EDS and WDS have the same spatial resolution; for the same incident electron energy, the volume of material that is sampled is identical. However, WDS has better spectral resolution; the width of the energy peak with WDS may be as low as 5 eV, compared to around 125 eV with EDS (Figure 10). The finer resolution of WDS is useful for eliminating problematic peak overlaps that may occur in EDS, for example, between manganese and iron, between oxygen and vanadium, and between sulfur, molybdenum, and lead. A dedicated WDS system is especially useful for routine examination of specimens containing those elements, such as ferrous alloys.

WDS also can detect smaller elemental fractions than EDS. While the ability to separate overlapping peaks certainly helps sensitivity, the benefit is primarily seen in trace element analysis. In WDS, the wavelength is set to that of the desired element; a fast acquisition rate is then used to obtain a high-intensity peak. The higher the peak, the higher the peak-to-background ratio, and the more accurate the quantification will be.

Figure 10 A comparison of the spectral resolutions of EDS and WDS. The blue EDS spectrum shows a single peak of width 260 eV, which identifies the presence of silicon. The superior resolution of WDS reveals the presence of tungsten as well as silicon. The widths of the WDS peaks are less than 40 eV. (Figure courtesy of EDAX Inc.)

Using EDS to identify an unknown material

A small object, found in commercially purchased processed meat, damaged a consumer's tooth. From its appearance, it was suspected that the object was a bit of hard plastic. To differentiate between animal bone, which may be expected in meat, and a foreign object, the object was examined with SEM and EDS. The chemical composition is shown in Figure 11(a). Calcium, expected in bone, was not present, but a high level of sulfur was. For comparison, two known samples, animal bone (Figure 11(b)) and two-part epoxy (Figure 11(c)), were also analyzed. The unknown object was determined to be a foreign material, a type of glue or epoxy, rather than bone.

x-Ray fluorescence

x-Ray fluorescence (XRF) determines bulk composition using x-rays to stimulate characteristic x-ray emission. In XRF, the maximum incoming x-ray energy varies with manufacturer and instrument configuration, but typically ranges from 50 to 60 kV. Detection of characteristic x-rays is done by one of the methods described above, either EDS or WDS, and with the same attendant advantages and disadvantages.

In XRF, specimen size, sampling volume, and preparation are additional considerations. XRF instruments typically require a large amount of specimen (1 g or more), with a sampling depth ranging from microns to millimeters, depending on the incident x-ray energy and atomic makeup of the matrix. In the electron microscope, EDS/WDS can be performed on smaller amounts of material, and the x-rays are emitted selectively from the top microns of the specimen surface. However, this selectivity may be disadvantageous in circumstances where the overall composition of an inhomogeneous specimen is needed. Due to the higher sampling depth, XRF is preferred for bulk analysis. In XRF, since morphology is not determined, specimens are commonly ground and pelletized to ensure a homogeneous mixture and a smooth surface.

Figure 11 EDS spectra for (a) unknown sample, (b) bone, and (c) two part epoxy.

Auger Electron Spectroscopy

The Auger emission spectroscopy (AES) technique is similar to EDS in signal production, but, instead of x-rays, it detects the low-energy electrons that are emitted during relaxation of an atom after ionization. When an outer shell electron drops down to fill an empty inner shell position, one way it can give up its excess energy is by transferring a portion of that energy to another outer shell electron. This low-energy electron (~ 20 – 2500 eV) is then ejected from the atom as an Auger electron.

AES is performed in ultra-high vacuum, around 10^{-9} torr (compared to 10^{-6} torr used in electron microscopy). The ultra-high vacuum keeps the specimen surface clean and allows the low-energy Auger electrons to travel to the detector without colliding with gaseous atoms. An electron beam is directed at the specimen surface, and the surface is oriented so that the emitted Auger electrons are directed into a detector. The most common detector for AES is a cylindrical mirror analyzer (CMA). The CMA consists of two concentric cylinders, each held at a different voltage, creating an adjustable electric field. Fine-tuning of this field directs high-energy electrons away from the detection apparatus, while aiming electrons in the desired low-energy range at an electron multiplier, where they are counted. A typical AES spectrum is shown in Figure 12.

AES is a true surface analysis technique; weak Auger electrons will not escape from the specimen except at the top

Figure 12 AES spectra of doped silicon nanowires. (Figure courtesy of D. Paul, Physical Electronics USA.)

Figure 13 FTIR spectra illustrating 1-octene hydrosilation. The sample is silicon with 1-octene. (a) Octane C–H stretch, (b) Si–H_x stretch X = 1–3, (c) possible Si–O–Si stretch, (d) CH bend. (Figure courtesy of R. Terrill, Department of Chemistry, San Jose State University.)

atomic layers of the surface, that is, the top few nanometers. Coupled with an ion gun for removing surface material, AES is an extremely sensitive technique for determining depth concentration profiles.

Absorption Spectroscopy

In absorption spectroscopy, electromagnetic radiation, generally in the ultraviolet–visible–infrared range of the spectrum, is directed at a specimen. Transmitted, scattered, and/or reflected radiation is detected, and changes in intensity with respect to wavelength are determined. A diminution in intensity signifies atomic absorption (Figure 13). As absorption corresponds to quantum-level changes in the specimen, for example, transitions between specific atomic or molecular energy levels, or changes in rotational or vibrational state, the elemental or compound composition may be determined from the specific wavelengths absorbed.

Generally, spectroscopic techniques track changes in light intensity with respect to the incident light intensity (Figure 14). The measurable quantities are the incident light intensity I_{Incident} and transmitted light intensity $I_{\text{Transmitted}}$. The fraction of light which is absorbed at a given wavelength is calculated from the measured incident and transmitted light intensity, by

$$I_{\text{Absorbed}}(\lambda) = (1 - I_{\text{Transmitted}}) \times I_{\text{Incident}}$$

Of course, reflected ($I_{\text{Reflected}}$) and scattered ($I_{\text{Scattered}}$) light intensity may also be determined. Various detectors are used depending on the wavelength of light being detected; photodiodes are typically used for visible and ultraviolet light.

Many spectroscopic techniques using infrared, visible, and ultraviolet light are available; these include infrared spectroscopy (IR), inductively coupled plasma atomic emission spectroscopy (ICP-AES), ultraviolet–visible spectroscopy (UV-Vis), Raman spectroscopy, atomic absorption spectroscopy (AAS), and x-ray photoelectron spectroscopy (XPS), also called electron spectroscopy for chemical analysis (ESCA). Further

Figure 14 In addition to being absorbed within the specimen, light is reflected from the front and back surface, and scattered at surface imperfections. The amount of absorbed light is calculated from the incident and transmitted light intensities.

information sources for spectroscopic techniques are provided in the References section.

Mass Spectrometry

In mass spectrometry (MS), a gaseous sample is ionized, then analyzed according to the mass-to-charge ratio (m/Z) of its components. Various techniques may be applied for sample vaporization, ionization, and ion detection, depending on the initial specimen and the desired information. In environmental

forensics, for example, typical specimens include sorbent from an air sampler, or a material suspected as a source of air contamination. In these cases, the samples are heated in an inert atmosphere, and any resulting effluent gas is ionized by impact with high-energy electrons emitted from a hot tungsten filament. The ions enter the mass spectrometer, and are acted on by a magnetic or an electric field; the resulting change in the speed and trajectory of an ion is due to the applied field strength and the mass, charge, and velocity of the particle. Detecting these changes allows m/Z to be calculated.

For further discrimination of chemical species, a common configuration is the gas chromatograph-mass spectrometer (GC-MS). The effluent is passed through a gas chromatograph, where a column packed with a high-surface-area material absorbs and desorbs chemical species at different rates. The column provides a temporal spread to the species before they enter the mass spectrometer to be enumerated according to their mass-to-charge ratio.

As with spectroscopy, additional spectrometry techniques are available, with different schemes for vaporizing and ionizing the sample, and analyzing the mass-to-charge ratio. These include inductively coupled plasma mass spectrometry (ICP-MS), time-of-flight mass spectrometry (TOF-MS), and secondary ion mass spectrometry (SIMS). Information sources are provided in the References section.

Analysis of process effluents using mass spectrometry

To determine whether blueprint paper could be a source of air contamination during a printing process, a sample of the paper was subjected to testing by heating; the resulting effluent gas

was analyzed in the mass spectrometer. The resulting spectrum is shown in **Figure 15**. A number of organic compounds were identified; the largest component was di-propylene glycol.

Thermal and Thermogravimetric Analysis

Differential thermal analysis (DTA) and differential scanning calorimetry (DSC) measure the heat input required to increase a specimen's temperature. The term differential is used since changes in the specimen are measured with respect to a standard reference material. In DTA, the differential temperature change between the specimen and reference for a fixed amount of heat input is measured (**Figure 16**). In DSC, the differential heat input required to increase the temperature of both the specimen and the reference is measured (**Figure 17**). In both cases, the specimen and reference are insulated from the environment in an adiabatic calorimeter.

In the related technique of thermogravimetric analysis (TGA), a small amount of specimen (milligrams) is heated in an inert or reacting atmosphere, and any resulting mass changes are measured with respect to temperature. For example, absorbed water will evaporate by around 100 °C. Bound or adsorbed water will evaporate by around 400 °C, so the degree of hydration may be determined. Decomposition reactions will occur at various temperatures depending on the material composition and atomic bonding.

TGA-DTA/DSC techniques maybe performed simultaneously, to determine the range of thermal characteristics with a single sample/run.

Figure 15 Spectrum obtained via heating and mass spectrometry. The major component of the gaseous effluent was di-propylene glycol.

Figure 16 DTA measures the differential temperature change between the specimen and reference for the same amount of heat input. Here the specimen is observed undergoing a phase transition.

Figure 17 DSC measures the differential heat input required to increase the temperature of both the specimen and the reference. Here the specimen undergoes both an endothermic and an exothermic reaction.

Selecting the Appropriate Technique

Only a small, or limited, selection of useful materials analysis techniques is presented herein; however, many more methods are available, which may be more or less appropriate to a particular investigation. The materials failure analyst must use his or her education, training, and experience to determine which techniques are required. In addition to selecting the appropriate technique, the analyst must give weight to all relevant considerations, including the use of destructive or nondestructive analysis, required specimen size, and specimen composition and characteristics.

Glossary

Arcing A discharge of electricity through a gas.

Burn patterns The damage caused by fire.

Circuit breaker A device designed to open and close a circuit by nonautomatic means, and to open the circuit automatically on a predetermined overload of current.

Conductor A substance or body that allows a current of electricity to pass continuously along/through it.

Electrocution The destruction of life by means of electrical current.

Exemplar Something that serves as a model or example.

Fuse An electrical safety device consisting of or including a wire or strip of fusible metal that melts and interrupts the circuit when the current becomes too high.

Lock out To open an electrical circuit and place a lock on it so that it cannot be closed without removing the lock.

Overhead Aerial utility power supply equipment to buildings or structures.

Panelboard A single panel or a group of panel units containing buses, switches, fuses, and/or circuit breakers for the control of light, heat, and power circuits.

Resistance The physical property of an element or device to resist/oppose the flow of electricity through it.

Service Electrical wires and/or equipment supplying electrical power to buildings or structures.

Specifications The design requirements.

Tripped The position of a circuit breaker's operating handle when it opens due to an overload current.

Underground Subterranean utility power supply wires and/or equipment to buildings or structures.

Investigation

The investigation of electrical phenomena began in Europe in the seventeenth century. The first electrical investigators were called electricians. One of the first electrical investigators was Benjamin Franklin. He made on-site inspections of churches which were struck by lightning. He wrote newspaper articles requesting information about lightning damage, and read articles about lightning damage to churches to determine the effectiveness of church bell ringing, which was believed to disperse lightning. Franklin found that bell ringing during a thunderstorm is a very dangerous occupation. There was no great need for electrical investigations until the inventions of Alexander Graham Bell's telephone in 1876 and Thomas A. Edison's incandescent lamp in 1878. Now we are surrounded by electrical fields, wiring, and devices which can, and do, cause injury or property damage.

The on-scene electrical investigation should be conducted as soon as possible after an event, before evidence is moved, discarded, or altered by repairmen, rescue workers, or first responders. The electrical investigator utilizes the same scene investigation techniques as the crime scene investigator, except that electrical items are the focus of the investigation. As a result, it is imperative that the electrical investigator have substantial practical knowledge about electrical equipment, wiring, and devices. Practical electrical knowledge is obtained through education and experience in designing, installing, maintaining, and repairing electrical devices, appliances, and equipment.

Before visiting the accident scene, any available information about the accident or suspected cause should be obtained from eyewitnesses, private investigators, insurance adjusters, police officers, firemen, first responders, and/or attorneys. The information could be used to confirm or refute what is

found at the scene. The suspected cause must be evaluated. Upon arrival at the scene, photographs should be taken of the area surrounding the accident. The electrical power service to the scene should be inspected and documented with photographs and/or diagrams. Is it a residential, commercial, or industrial overhead or underground electrical service? Is there any evidence of recent work and/or repair to the exterior electric service?

Next, the investigator must determine the origin of the electrical accident. Sometimes the origin is where the greatest amount of damage is found. However, combustible materials in the area could cause severe damage remote from the origin. This is where the information obtained from eyewitness accounts might be helpful.

If an area of origin cannot be determined, all the electric lines/wires passing through damaged areas should be inspected. The investigator should be looking for evidence of electrical arcing or short circuiting on the wires. Electrical arcing or short circuiting generates temperatures in the range of 3000–20 000 °C. It is the heat generated by the arcing or short circuiting of electricity that causes most electrical damage and injury. The wires are normally made of copper or aluminum. Copper melts at 1083 °C and aluminum at 570–660 °C. Normally, fires do not generate sufficient heat to cause copper to melt. Therefore, the copper wiring will remain intact except for the insulation, which might have burned away. Evidence of melting on copper wiring indicates that electrical arcing or short circuiting may have occurred at the melted location. Photographs should be taken to document the area surrounding the melted wiring and close-up photographs of the melted wires. Aluminum wiring is quite frequently found melted by a fire, as fires can, and do, generate sufficient heat to melt aluminum. Subsequently, melted aluminum wiring may not be evidence of electrical arcing or short circuiting. Any melted

aluminum wiring should be photographed in place. Wiring suspected of short circuiting or arcing should be retained for further analysis. As much as possible the wiring should be retained, especially undamaged sections which may contain manufacturer's labeling and specifications. All sources of electrical power to the accident area should be inspected and photographed. If damage is found upon power supply components, they should be retained for further analysis. All fuses should be tested with a continuity tester to determine if they have opened. The position of all circuit breakers should be documented as to whether they are 'on/off' or in a middle 'tripped' position. Evidence of overheating on power supply components, a blown fuse, or tripped circuit breaker might aid in the determination of the accident's origin. All electrical devices in the damaged area should be inspected for evidence of internal damage, which could indicate the origin of the problem. In addition, the installation and condition of undamaged electrical equipment in the vicinity of the accident should be inspected. The undamaged equipment might reveal an installation or component problem that caused the electrical accident.

If the area of origin can be determined, it should be photographed from various angles before anything is moved. Everything electrical should be retained from the area of origin and labeled to identify where it was found at the scene. Manufacturer's labels and specifications on electrical equipment should be documented. If a specific electrical device or product is suspected of causing the accident, the accident area should be searched for a similar device, product, or installation.

An exemplar product or installation could reveal what precipitated the accident. The source of electrical power to the origin should be inspected and traced back through the electrical distribution system to where it obtains electrical power. The fuse and/or circuit breaker protecting the distribution system should be inspected and photographed. Any damage to the fuse and/or circuit breaker would require that it/they be retained. They should also be retained if evidence of electrical arcing, short circuiting, or conductor overheating was found in their vicinity. The distance from the fuse and/or circuit breaker to the area of origin should be documented/measured. If the distance is too long, the circuit breaker or fuse will not provide adequate protection. The resistance of a long circuit reduces the fault current through it and impedes the operation of a circuit breaker or fuse.

Electrical conductor overheating is another way electricity can cause damage by igniting combustible materials in contact with it.

Electrical conductor overheating is normally prevented by a fuse or circuit breaker that opens and removes electrical current from the conductor before it overheats. However, sometimes the fuse is too large (mismatched) for the conductor or the circuit breaker fails to properly operate.

The size of the fuses or circuit breakers should be documented, as well as whether any of the fuses opened or circuit breaker positions were 'on/off' or 'tripped.'

The investigation should be conducted with no electrical power feeding into the accident area. The investigator should have a voltage detector to verify that there is no electrical power. A continuity tester would facilitate determining which fuse or circuit breaker fed electrical conductors in the area of

origin or if a switch is open or closed. Small digital microscopes that operate with laptop computers provide excellent close-up photographs of electrical devices. A quality 3 charge coupled device progressive scan video camera can provide excellent video of the accident scene and show items from a different perspective than a still photographic camera. It will also bring your audience into the accident scene. Small hand tools are required to open up electrical devices such as panelboards, receptacles, switches, and fixtures. Wire cutters of various sizes are a necessity. A wire caliper would be useful in determining the size of electrical wiring. A very bright light source such as a high-power light-emitting diode flashlight will aid the investigation.

When photographing electrical wiring or components, a dark blue cloth used as a background will produce the best-quality photographs.

Electrical devices retained from the scene should be opened to inspect their internal components for evidence of electrical arcing, short circuiting, or overheating. The exterior of the devices should be photographed before disassembly begins and during various phases of the disassembly. However, if a device cannot be disassembled without altering its appearance, it should be x-rayed to examine its internal components. X-rays will normally show evidence of electrical arcing or short circuiting within the electrical devices. However, the x-rays will not show evidence of overheating. The x-rays will aid in the destructive examination/disassembly of the device.

If the electrical accident involves personal injury or death, the medical records should be obtained to determine the injuries sustained by each victim. Electrical entry and exit wounds, degree of burns, and their locations are normally reported. A low-voltage electrical shock (120 V alternating current or less) might not leave an entry or exit wound, especially if water is involved. The water cools the area and prevents burning of the flesh. The medical records may indicate significantly elevated serum creatine phosphokinase levels due to the muscle contractions caused by the electrical current if the victim remains in the circuit for seconds or minutes while alive. The clothing worn by the victim(s) at the time of the incident should be examined, including their footwear. Any protective clothing and gear should be retained for further examination/analysis. The type of flooring in the accident area should be documented along with the environmental conditions. Architectural plans, construction drawings, and permits of the accident area should be obtained.

An Internet search may reveal videos or photographs of the accident taken by eyewitnesses. Sometimes exemplars, manufacturer's operation manuals, and drawings can be obtained through the Internet. Complaints concerning the product or service might be posted online or at websites such as the Consumer Product Safety Commission.

Analysis

Electrical wiring can melt as a result of a eutectic reaction, which is the lowering of the melting temperature of a metal by a melted metal having a lower melting temperature. The eutectic melted wire can resemble an electrical short circuit or arcing damage. A metal such as aluminum, which melts due to

fire exposure, can fall onto copper wiring and cause it to melt, as well. Elemental analysis of the melted areas by scanning electron microscopy/energy dispersive x-ray spectrometry can determine if there is foreign metal present in the melt. If electrical arcing or short circuiting is confirmed, 'arc mapping' can be conducted to aid in the determination of the accident's origin. Arc mapping involves plotting the location of arcs or short circuits on a diagram of the accident area. The arc or short circuit that is found furthest downstream from the source of electrical power most probably is closest to the origin of the problem as it was the first location where the electrical system sustained damage. Upstream electrical short circuits would prevent the occurrence of downstream short circuits, if they occurred first. Consequently, electrical short circuiting or arcing found at the point of the accident's origin downstream from the power source is most probably the initial location of the commencement of the accident. The reason for the arcing or short circuiting should be determined. Did the installation of the wiring meet the requirements of the local electrical codes? In most of the United States, the National Fire Prevention Association's (NFPA) National Electrical Code (NEC) applies to the installation of electrical wiring in residential and commercial buildings. The National Electrical Safety Code (NESC) applies to the installation and maintenance of electric utility wiring and distribution equipment. Many large cities and states have their own electrical codes which follow the requirements of the NEC and the NESC with more stringent requirements.

The x-rays of a suspected defective circuit breaker should be evaluated with design drawings or the x-rays of a properly functioning exemplar circuit breaker. If no discrepancies are found, the circuit breaker should be tested to determine whether it meets the requirements of its certifying laboratory (Underwriters Laboratory, Inc. for low voltage in the United States of America). The National Electrical Manufacturers Association, NEMA, and IEEE have standards which apply to low-voltage and high-voltage circuit breakers that could be of use in an investigation. The testing should be done prior to disassembly of the circuit breaker because it is very difficult to reassemble a circuit breaker exactly as it was prior to disassembly. After testing, the circuit breaker should be disassembled in order to inspect/examine the internal components for evidence of overheating and arcing, which might not be apparent in the x-rays.

Testing should be performed on protective components in electrical equipment and devices to verify that they function as designed. These safety components may be intended to protect against overcurrent, overvoltage, under voltage, temperature limiting, liquid level control, or ground fault protection.

Construction specifications, work invoices, and daily job site reports may be useful in the analysis. The building codes of NFPA, American Society for Testing and Materials, and The International Building Code may also assist in the analysis of the accident scene.

Casework/Examples

The first example involves an electrical accident or more appropriately an electrical incident which occurred at a sporting

club. The incident originated at an outdoor racquetball court (Photograph 1). A 12 kV electrical power line had dropped down and made contact with the metal screen around the racquetball court (Photograph 2). The power line continued down and burned a hole in the metal floor of the racquetball court (Photograph 3). Luckily, no one was utilizing the racquetball court at the time of the incident. Severe damage was found underneath the racquetball court where oil heaters and fans were located to heat the court as it was located in a temperate climate location (Photograph 4). None of the fuel ignited even though there was evidence of electrical arcing surrounding the fuel storage tank (Photograph 5). An electrical panelboard near the racquetball court was completely destroyed (Photograph 6). The metal siding on a club house located ~3 m from the court was damaged by electrical arcing (Photograph 7). The ground conductors of various appliances that were plugged in at the time of the incident were burned away. Ground conductors of wiring within the club house were damaged (Photograph 8) and evidence of electrical arcing was found on a fuel line (Photograph 9). Fortunately, the fuel in the line did not ignite.

Photograph 1 Electrical incident at an outdoor racquetball court.

Photograph 2 Electrical power line dropped down and made contact with the metal screen around the racquetball court.

Inspection of the area surrounding the sporting club found that the local utility was installing power line poles and power lines at the time of the incident (**Photograph 10**). There were

Photograph 3 The power line burned a hole in the metal floor of the racquetball court.

Photograph 4 Severe damage was found underneath the racquetball court.

Photograph 5 Evidence of electrical arcing surrounding the fuel storage tank.

Photograph 6 The metal siding on a club house damaged by electrical arcing.

Photograph 7 An electrical panelboard near the racquetball court completely destroyed.

Photograph 8 Ground conductors of wiring within the club house were damaged.

no environmental factors that could have caused the line to fall as the weather was clear at the time of the incident.

Subsequently, the power line most probably fell down as a result of the work activity in the area by the utility company.

The damage was the result of installing an electric power line above the metal racquetball court in violation of electrical code requirements. The NESC requires a vertical clearance of 3 m above the metal racquetball court and a horizontal clearance of 2.4 m.

The next example involves a wildland fire. A wildland fire is a fire which originates in an uninhabited area of land. It might subsequently spread and damage/destroy inhabited buildings and areas of land. Inspection of the burned land areas indicated that the fire originated near a utility electric pole (Photographs 11 and 12). The utility pole was made of wood (Photograph 13). Two levels of power lines were on the utility pole with 69 kV lines at the top (Photograph 14). Inspection of the power lines found splices in the power lines (Photograph 15). The power lines crossed over a gully where burning was still occurring underneath a 12 cm layer of ash at the time of the investigation (Photograph 16). The power lines

were traced to the utility substation which controlled them. The wildland fire had destroyed vegetation and buildings in its path as it spread (Photographs 17 and 18). Electrical ground conductors were found severely heat-damaged in buildings that were not ignited by the fire as the result of an electrical power surge (Photographs 19 and 20).

Photograph 11 Inspection of the burned land areas indicated that the fire originated near a utility electric pole.

Photograph 9 Evidence of electrical arcing was found on a fuel line.

Photograph 12 Closer perspective of burn patterns near utility poles.

Photograph 10 Area surrounding the sporting club found that the local utility was installing power line poles and power lines at the time of the incident.

Photograph 13 The utility pole made of wood.

Photograph 14 Two levels of power lines were on the utility pole with 69 kV lines at the top.

Photograph 15 Inspection of the power lines found splices in the power lines.

Photograph 16 The power lines crossed over a gully where burning was still occurring underneath a 12 cm layer of ash at the time of the investigation.

The weather in the area was extremely dry with very little rainfall and at sunset the wind would pick up, sometimes exceeding 100 km h^{-1} .

Photograph 17 The wildland fire had destroyed vegetation and buildings in its path as it spread.

Photograph 18 The contents of some buildings were completely destroyed as the fire spread.

Photograph 19 Electrical ground conductors were found severely heat-damaged in buildings that were not ignited by the fire as the result of an electrical power surge. Arrow in the photograph indicates the ground conductors.

Information was obtained from the utility company concerning protective devices in the utility substation meant to protect the power lines located in the area of the fire's origin. The lines were protected by an electrical recloser. A recloser is a device that senses an electrical problem on a power line such as

contact with a tree branch. The recloser will momentarily remove electrical power from the line and then attempt to reclose it in order to restore electrical power if the problem has gone away. The number of attempts the recloser will make is determined by its settings. After a set number of attempts have been tried without success, the recloser will lock out and prevent further power from flowing through the power lines that it protects. To reenergize the power lines, a utility worker must manually reclose the recloser at the utility power substation. The records for the subject recloser indicated that it had locked out and been manually reclosed twice. Depositions of the utility workers revealed that on the night of the fire, one individual was at the utility power substation manually closing the recloser while another worker was on a hill looking to see where the power lines sparked or arced in the darkness. Both utility workers ran from the area after realizing they had ignited a wildland fire.

This fire was the result of the inappropriate action by the utility workers. The utility workers should have walked along the power lines inspecting them until they located the problem with the power lines.

Manually closing the recloser after it had locked out without inspecting the power lines resulted in this fire.

The power line came down because the wind in the area after sunset quite frequently exceeded the capacity of the components on the wooden utility pole in the area of fire origin. The wooden poles were replaced with metal poles that have a higher wind capacity and they look like wooden poles from a distance.

The third case study involves a serious electrical injury to a maintenance worker. The maintenance worker had been assigned the task of cleaning the roof gutters on a large three-

story building utilizing a motorized manlift (**Photograph 21**). The manlift was rented from a local company and they brought the manlift to the building location for the maintenance worker to use. The maintenance worker proceeded to clean the gutters of the roof and while lowering the manlift at one point, his head made contact with a 12 000 V power line. The 12 000 V power line was in close proximity horizontally to the building and ~2 m below the level of the roof gutters. The ground sloped away from the building, which required the manlift to have something to stabilize it when the platform is raised. The manlift had warning labels on it (**Photograph 22**) which read: 'Danger electrocution hazard.' 'Do not operate this machine unless you have been trained in the safe operation of this machine.' 'Training includes complete knowledge of safety and operating instructions contained in the manufacturer's manuals.' 'This machine is not insulated.' 'You must maintain a clearance of at least 10 feet between any part of the machine or load and any electrical line or apparatus charged up to 50 000 V.'

The tires and base of the manlift were in contact with wet vegetation near the perimeter of the building, which provided a high-resistance current path from the lift's base to the ground (**Photograph 23**). This manlift did not have outriggers on it. Outriggers are devices which extend from the base of the lift in

Photograph 20 Heat damaged ground conductors are indicated by the arrow in the photograph.

Photograph 21 The maintenance worker cleaning the roof gutters on a large three-story building utilizing a motorized manlift.

Photograph 22 Warning labels on the manlift.

order to provide stability, particularly when the lift platform is raised. Outriggers are normally made of metal, which would have provided a low-resistance current path from the lift to the ground. The operator's platform could be entered through a metal gate on the platform (Photograph 24). Inspection of the interior side of the entrance gate revealed evidence of burning and clothing material adhering to it (Photograph 25). Evidence

Photograph 23 The tires and base of the manlift were in contact with wet vegetation near the base of the building.

Photograph 24 The operator's platform could be entered through a metal gate on the platform.

Photograph 25 Inspection of the interior side of the entrance gate revealed evidence of burning and clothing material adhering to it.

of burning was also found on the frame of the platform near the operator's controls (Photograph 26). The operator's controls were covered with spackling materials (Photograph 27). An unlabeled black box was found on the platform which was also covered with spackling materials (Photograph 28). Cleaning the roof gutters did not involve the use of spackling materials. The spackling material covered the latches of the box and verified that it had not been opened by the maintenance worker. The unlabeled black box contained the manlift manufacturer's instruction book/user's manual for the safe operation of the lift.

Evidence of burning found on the interior side of the entrance gate and on the frame near the operator controls indicates that electricity exited the maintenance worker's back

Photograph 26 Evidence of burning was also found on the frame of the platform near the operator's controls.

Photograph 27 The operator's controls were covered with spackling materials.

Photograph 28 An unlabeled black box was found on the platform which was also covered with spackling materials.

and left hand. Twelve thousand volts contacting the head of a person and exiting out their back and hand would normally electrocute them. However, the tires of the lift provided some isolation (high resistance) to the flow of electricity through the manlift to the ground. A manlift with outriggers should have been supplied by the rental company as the land around the perimeter of the building sloped away from it causing the manlift to be unstable when the platform was raised. However, metal outriggers would have provided a low-resistance path through the manlift to the ground and would have resulted in his electrocution. Instead, the worker was seriously burned and unconscious for more than a month. This incident was the result of the use of inappropriate equipment in a hazardous area by maintenance workers who were not aware of the hazards or not appropriately trained to perform the work.

The next case study is severe burn injuries that a building maintenance worker received from electrical arcing while attempting to change a door on a motor control center.

An electrical contractor had installed capacitors on a motor control center to improve the power factor of the electricity coming into the building (**Photograph 29**). Electric utilities quite frequently charge their customers additional fees for bad electrical power factors. Power factor is the ratio of total watts to the total root-mean-square of volt-amperes. A disconnect switch for the capacitors was installed at the bottom of the motor control center (**Photograph 30**). The electrical contractor did not install the correct door to operate the capacitor disconnect switch in the bottom unit. Subsequently, the contractor asked a maintenance worker of the building to replace the door with the correct unit. The motor control center had warning labels on it.

Photograph 29 An electrical contractor had installed capacitors on a motor control center to improve the power factor of the electricity coming into the building.

One warning label stated: “DANGER: hazard of electrical shock or burn. TURN OFF POWER supplying this equipment before working inside” (**Photograph 31**). Another warning label stated: “TURN OFF POWER AT UTILITY before working behind this cover. The line side bus of any main breaker or switch remains energized when the main is in the off position” (**Photograph 32**). A manufacturer’s label on the motor control center indicated that the voltage within it was 277/480 V, three phase, and it had a current rating of 2000 A (**Photograph 33**). The cardboard covering the bottom opening of the motor control center was removed and evidence of burning and arcing was

Photograph 30 A disconnect switch for the capacitors was installed in the bottom of the motor control center.

Photograph 32 Another warning label.

Photograph 31 Warning labels on the motor control center.

Photograph 33 Manufacturer's label on the motor control center indicating that the voltage within it was 277/480 V, three phase, and it had a current rating of 2000 A.

found within it (Photograph 34). The disconnect switch that was previously located in the burned opening had been retained (Photograph 35). Electrical arcing burned a hole through the steel at the top of the unit and through its back (Photograph 36).

The building maintenance worker was not an electrician. He had no knowledge of the hazards involved in working within this motor control center. He was not wearing any personal protective equipment such as eye goggles, face shield, insulating gloves, insulating sleeves, or insulated safety hat. When he was trying to change the door on the capacitor control compartment, his screwdriver slipped and made contact between a charged 277 V component and the grounded enclosure. This caused an arc blast within the unit that vaporized copper and steel components of the compartment. As he was bending over in front of the compartment at the time, he was severely burned from the top of his head to his waist.

To safely change the door on the motor control center, electrical power would have to be turned off at the electrical utility's supply point and locked out. The capacitors should be discharged and the power supply conductors grounded to drain off any residual electrical charge within them, prior to attempting maintenance work.

The fifth example/case study is an electrocution which occurred at a luxury hotel. The hotel had four ways of traveling from its registration desk to its guest rooms; walking, golf cart, boat, or electric train (Photograph 37). A maintenance manager at the hotel had found a loose cover over the electric train track which passed through a pedestrian walkway (Photograph 38). The walkway was wet as the canal for the boat system was located in close proximity 2 m away. The

maintenance manager was concerned that a guest might slip and fall and hurt themselves. Therefore, he attempted to tighten bolts which held the covers in place (**Photograph 39**). While reaching underneath the train track cover, he was electrocuted.

Photograph 34 The cardboard covering the bottom opening of the motor control center was removed and evidence of burning and arcing was found within it.

Photograph 35 The disconnect switch that was previously located in the burned opening had been retained.

Photograph 36 Electrical arcing burned a hole through the steel at the top of the unit and through its back.

Photograph 37 The hotel had four ways of traveling from its registration desk to its guest rooms: walking, golf cart, boat, or electric train.

Photograph 38 A maintenance manager at the hotel had found a loose cover over the electric train track which passed through a pedestrian walkway.

Photograph 39 The maintenance manager attempted to tighten bolts which held the covers in place.

Examination of the underside of the train revealed that it received electrical power from electrical bus bars energized with 480 V of alternating current beneath it (Photograph 40). Electrical contact shoes (Photograph 41) would slide in a groove of the bus bars as the train moved along its track to obtain power for its traction motors (Photograph 42). An electrical joint compound was utilized to reduce the electrical resistance between the bus bars and electrical shoes (Photograph 43). No evidence was found that the manager made contact with the bus bars. However, an electrical joint compound which conducts electricity was found between the bus bars and bolts that held the train track cover in place. Subsequently, the man was electrocuted when he touched the electrical joint compound while kneeling on the wet concrete walkway which grounded him. Electrical current entered his body through his hand, passed through his heart, and exited out his knees, killing him.

Photograph 40 Examination of the underside of the train revealed that it received electrical power from electrical bus bars.

Photograph 41 Electrical contact shoes.

The sixth and final case study is that of a church fire (Photograph 44). This church was utilized by two different denominations, with differing beliefs, and an arsonist was known to be active in the area. A clockwise inspection of the church exterior found smoke residue around an opening along its base near the northeast corner (Photograph 45). Examination of the burn patterns within the church indicated that the fire originated in the northeast corner below the first pew (Photographs 46 and 47). Electrical copper and aluminum wiring was found passing through the area of fire origin (Photograph 48). Fused disconnect switches located in the

basement of the church supplied electrical power to the wiring which passed through the area of origin (**Photograph 49**). One fused disconnect switch was missing its fuses and the aluminum wiring previously attached to it had been cut off (**Photograph 50**). Heat damage was found on the cut-off wires (**Photograph 51**). The manufacturer's label on the inside of the fused disconnect switch was clearly heat-damaged (**Photograph 52**). The aluminum wiring was traced to a second-floor gymnasium attached to the church that was utilized to play basketball. The aluminum wiring was spliced within a junction box in the gymnasium that fed power to an electrical receptacle. When the junction box was opened, a distinct odor of burning electrical insulation was detected and evidence of overheating was found on the spliced wiring (**Photograph 53**). The insulation of the aluminum wiring attached to the receptacle showed evidence of overheating (**Photograph 54**). The receptacle had a room air conditioner plugged into it that did not have the capacity to cool the gymnasium. Therefore, it would draw its maximum rated current when turned on. Testing of the air conditioner found that its compressor motor had shorted out and it would draw more current than rated when turned on. On the day of the fire, there was basketball practice in the gymnasium and the temperature outside the building exceeded 38 °C.

Electricians making repairs in the church were contacted and the fuses previously located in the fused disconnect switch were obtained (**Photograph 55**). The fuses were rated at 100 A and showed evidence of overheating, but they had not opened. The aluminum electrical wiring that they protected was rated at 50 A. The 100 A fuses would not properly protect the 50 A wiring and the resistance of the excessively long circuit limited the fault current. Consequentially, the fire was caused by overheated aluminum wiring that passed through the area of fire origin where heat was entrapped by wooden framing, which eventually ignited.

Glossary

Deceleration trauma When a body being in motion is forcibly stopped, the inner organs tend to continue the movement due to inertia so that the anatomical structures are subjected to tractive and shearing forces.

Fat embolism The term 'fat embolism' indicates the presence of fat globules in the small vessels of the lungs and sometimes also in the systemic circulation, mostly as a consequence of major bone and/or soft tissue trauma.

Hematotympanum The term refers to the presence of blood in the tympanic cavity of the middle ear, often

resulting from a basal skull fracture involving the petrous bone.

Lucid interval A temporary improvement after a head trauma followed by secondary deterioration (typically caused by a space-occupying intracranial hematoma).

Subarachnoid space This term describes the interval between the arachnoid membrane and the deeper pia mater (two meninges surrounding the brain and the spinal cord). The subarachnoid space normally contains the cerebrospinal fluid. In head injuries or as a consequence of a ruptured cerebral aneurysm, a hemorrhage may spread into the subarachnoid space leading to elevated intracranial pressure.

Introduction

The term 'blunt trauma' can be defined as damage to the body due to mechanical force applied either by the impact of a moving blunt object or by movement of the body against a hard

surface, both mechanisms resulting in the transfer of kinetic energy high enough to produce an injury (mainly by compression, traction, torsion, and shear stresses). Blunt-force injuries occur in criminal assaults (e.g., a blow with a blunt-edged instrument, a punch, or a kick), in physical child abuse, in traffic

and industrial accidents, in suicides (a jump from a height), and in accidental falls brought about by the victims themselves.

Blunt Injuries to the Integument

Abrasions

Abrasions are superficial injuries to the skin characterized by a traumatic removal, detachment, or destruction of the epidermis, mostly caused by friction. In the so-called tangential or brush abrasions, a lateral rubbing action scrapes off the superficial layers of the skin (e.g., from the body's sliding across a rough surface) and leaves a denuded corium, which is initially covered with serosanguineous fluid. In fresh grazes, the direction of impact can often be determined by the abraded epidermal shreds that remain attached to the end of the scrape. At a later time, the tissue fluid dries out and forms a brownish scab. If the lesion does not reach the dermis, it heals within several days without scarring. Infliction just before or after death results in a leathery ('parchment-like') appearance with a yellowish-brown discoloration (Figure 1).

Another type of abrasion is caused by a vertical impact to the skin (the so-called pressure or crushing abrasion). In such cases, the injuring object may be reflected by the shape of the skin injury so that the patterned abrasion can be regarded as an imprint of the causative object.

Contusions

Contusions or bruises are extravasations of blood within the soft tissues originating from ruptured vessels as a result of blunt trauma. In this context, only the contusions that are visible externally are considered. Textbooks usually differentiate between intradermal and subcutaneous bruises. In the first-mentioned category, the hemorrhage is located directly under the epidermis, that is, in the corium. This kind of superficial hematoma is usually sharply defined and red, whereas the more common bruises of the deeper subcutaneous layer have blurred edges and, at least initially, a bluish-purple color.

Figure 1 Tangential abrasion confined to the upper layers of the skin. The shreds of epidermis indicate the direction of impact. The central parts of the denuded corium show a parchment-like discoloration from drying.

Intradermal bruises may reflect the surface configuration of the impacting object (Figure 2). The skin that is squeezed into grooves will show intradermal bleeding, whereas the areas exposed to the elevated parts remain pale. Especially in falls from a height, the texture of the clothing may produce a pattern of intradermal bruises corresponding to the weaving structure. Patterned extravasations of this type are also seen in tire tread marks when an individual is run over by a wheel, and in bruises from vertical stamping with ribbed soles.

Subcutaneous bruises are usually nonpatterned. Nevertheless, there may be bruising of special significance. If the body is struck by a stick, a broom handle, a pool cue, a rod, or any other elongated instrument, every blow leaves a double 'tram-line' bruise consisting of two parallel linear hematomas with an undamaged zone in between. Victims of blunt force violence often sustain contusions from self-defense, typically located on the ulnar aspects of the forearms and on the back of the hands. The upper arms may show groups of roundish bruises from fingertip pressure in cases of vigorous gripping. A periorbital hematoma ('black eye') is induced either by direct impact (e.g., a punch or a kick) or indirectly (due to seepage of blood from a fractured orbital roof, a fractured nasal bone, or from a neighboring scalp injury of the forehead; Figure 3).

In general, bruises are regarded as a sign of vitality indicating that the contusion was inflicted prior to death. During life, the blood from ruptured vessels is forced into the soft tissue by active extravasation. Nevertheless, to a limited extent, postmortem formation of contusions is possible due to passive ooze of blood. In surviving victims, a deep bruise may not become apparent on the skin until several hours or even days later because of the slow percolation of free blood from the original site to superficial tissue layers.

In a living person, the contusion undergoes a temporal series of color changes. Initially, most subcutaneous bruises appear purple-blue. As the hematoma resolves during the healing process, the hemoglobin released from the red blood cells is chemically degraded into other pigments such as hemosiderin, biliverdin, and bilirubin. The color changes – usually over the course of several days – to green and yellow before it finally disappears (Figure 4). However, the rate of change is quite variable and depends on numerous factors, above all, the extent of the bruise.

Figure 2 (a) Intradermal bruising corresponding to the ribbed sole pattern of the perpetrator's training shoes (b). The imprint was caused by stamping actions against the face and neck of the victim lying on the ground.

Figure 3 Periorbital hematoma of a live victim from a blow to the left frontal region. As a result of gravitational movement, the blood from the injured forehead spread to the eyelids within 1 day.

Figure 4 'Black eyes' inflicted by a single fist blow to the root of the nose (6 days before the photograph was taken). Note the yellow color on the periphery of the bruises.

The size of an intradermal or subcutaneous hematoma is not always indicative of the intensity of the force applied to the affected area. Elderly people or patients suffering from bleeding diathesis may get bruises from slight knocks or for other minor reasons. On the other hand, the absence of an externally visible injury does not necessarily mean that there was no relevant trauma. Subcutaneous bruises of surviving victims are often followed by gravity shifting of the hemorrhage leading to a secondary downward movement of the hematoma.

A special type of blunt injury to the soft tissues is frequently seen in pedestrians who have been struck or run over by motor vehicles. Both the skin and the subcutaneous layer may be avulsed from the underlying fascia or bones by shearing forces so that a blood-filled pocket is formed, typically in combination with a crush damage to the adjoining fatty tissue.

Figure 5 Occipital region of a 41-year-old man showing a slit-like laceration of the scalp surrounded by a reddish excoriation. The injury was caused by a fall on a concrete step when climbing over the balustrade of a balcony.

Lacerations

Lacerations are tears of the skin or of internal organs (see below). They may be caused by blows from blunt objects (such as a hammer, a whipped pistol, a rod, the toecaps of heavy footwear, or a fist); other lacerations are produced by impact from vehicles or by a fall to the ground. Lacerations occur most commonly in body regions where the integument directly overlies a firm bony base acting as support (scalp, face, back of the hand, and shins). When the force acts on the skin, the subcutaneous tissue is squeezed between the injuring object and the bony platform so that the integument is compressed and crushed until it tears and splits sideways (**Figures 5 and 6**).

Lacerations are characterized by abraded, bruised, and crushed wound margins. The edges of the tears are typically irregular and ragged with bridging tissue strands (vessels, nerves, and fibers) running from side to side. The wound slits may be linear (especially in blows with a narrow, edged instrument), Y-shaped, or star-like. If the impacting object hits the skin at an oblique angle, one of the edges will be ripped away resulting in unilateral undermining (undercutting and avulsion), which indicates the direction of the force. Sometimes foreign material from the causative instrument/surface is deposited in the depth of the wound slit. The abrasion surrounding the tear may correspond to the shape and dimensions of the impacting blunt-surfaced instrument or – in the case of a fall to the ground – the area of contact.

Head Injuries

The head is a common target in assaults with blunt objects; other common causes of head injuries are traffic accidents, falls from a height, and falls from a standing position. The area of impact usually reveals injuries of the scalp or the facial skin, but it has to be stressed that severe and even lethal traumatization is not necessarily associated with scalp bruising, marked swelling, excoriation, and/or laceration. There may be no externally visible signs, especially in skin areas covered with hair and in cases of a fall onto a flat surface. An impact site on the vertex suggests that the head sustained a blow, whereas, in falls

Figure 6 (a) Occipital region of a 27-year-old man, whose scalp had been shaved before autopsy, showing four lacerations from blows with an empty 3-l champagne bottle (b). Note the bridging tissue strand between the wound margins.

Figure 7 Fatal head trauma caused by a fall on the occiput. External examination of the scalp had only shown an inconspicuous skin abrasion and a shallow laceration (a). From this area of impact, linear fractures extended to the base of the skull (b).

from standing positions, the scalp injuries are expected at the level of the brim of the hat.

Skull Fractures

These may involve the cranial vault, the base of the skull, and the facial skeleton. Although the presence of a skull fracture indicates severe traumatization, the fracture itself rarely threatens the victim's life. There are several types of skull fractures to be distinguished.

Single or multiple *linear fractures* are caused either by a blow with an object with a broad flat surface area or by a fall on the head so that the skull is deformed (flattening/indenting at the point of impact and outward bending/bulging in the periphery). The fracture lines originate where the bone is bent outwards and therefore is exposed to traction forces exceeding the limits of the bone's elasticity; from these extruded parts of the skull, the fractures extend toward the area of impact, and also in the opposite direction. For this reason, either of the ends is often in congruity with the impact injury of the scalp. Several fracture lines may radiate outward from a

central point of impact (Figure 7(b)) where the skull is often depressed and/or shattered to pieces forming a *spider's web* or mosaic pattern consisting of circular and radiating linear fractures (Figure 8). The sequence of skull injuries may be determined according to Puppe's rule: a later fracture does not cross a preexisting fracture line but terminates when reaching an earlier one.

Before fusion of the cranial sutures (i.e., in children and young adults), a fracture may travel along the seam resulting in diastasis (*diastatic fractures*). If a gaping fracture runs from one side of the cranial base to the other (mostly after lateral impact or side-to-side compression), this transverse type is called a *hinge fracture* because of the independent movement of the front and rear halves of the skull base.

Longitudinal fractures of the base of the skull often occur due to a fall on the occiput; in such instances, the linear fractures typically run through the posterior fossa either ending near the foramen magnum (Figure 9) or extending to the floor of the middle and anterior fossa. On the other hand, longitudinal fractures of the base can also be produced by impaction of the frontal region.

Figure 8 Frontal bone (squama) with linear fractures radiating outward from the area of impact and several additional circular fractures ('spider's web') – a 70-year-old car driver in a head-on collision.

Depending on its course and location, a *base fracture* may be followed by several *clinical signs*: bleeding from the ear (in fractures of the temporal bone with concomitant hematotympanum and rupture of the eardrum); bleeding from the nose and mouth (in fractures involving paranasal sinuses, which provide a communication with the nasopharynx); periorbital hematoma (from fractures of the orbital roofs); leakage of cerebrospinal fluid coming out of the nose or the ear (if the dura is injured along the fracture); and bacterial infection of the meninges (by spread from the nasal cavity, the paranasal sinuses, and the middle ear, especially when the fracture is accompanied by a tear of the dura).

Some special types of skull fractures can only be mentioned briefly. A *ring fracture* is located in the posterior fossa and encircles the foramen magnum. It occurs mostly in falls from a height onto the victim's feet or buttocks so that the cervical spine is driven into the skull. Another mechanism is seen in deceleration traumas, for instance, in head-on collisions, in passengers with fastened seat belts: Due to inertia, the non-restrained head will continue to move forward exerting traction forces on the base of the skull.

Bone impressions and *depressed fractures* are always localized at the point of impact where the head is struck with an object having a relatively small surface area such as a hammer or a protruding corner of a piece of furniture. The outline of a clean-cut defect in the outer table may reproduce the shape and size of a sharp-edged instrument. If only limited force is applied, the depressed fracture can be restricted either to the outer or, less often, to the inner table of the skull (the latter with inward displacement of the bone fragments). A depressed fracture from a blow that struck the skullcap at an angle may be concentrically terraced. *Hole fractures* from bullets perforating a flat bone of the skull are mostly roundish and clean-cut at the site of entrance, but beveled out in a crater-like manner, at the exit site.

Blunt force applied to the occiput, mostly as a consequence of a fall on the back of the head, often causes independent fractures of the anterior cranial fossa such as cracks of the thin orbital roofs (*secondary fractures* at the site of the contrecoup; cf. [Figure 9](#)).

Figure 9 Base of the skull with linear fracture in the posterior fossa sustained in a fall on the occiput. Note the presence of secondary fractures in the anterior fossa floor.

Intracranial Hemorrhages

A space-occupying bleeding into the brain membranes is followed by local displacement of the brain and raised intracranial pressure with concomitant flattening of the cerebral hemispheres. Intracranial hematomas as well as traumatic brain swelling, which often accompanies head injuries, may result in transtentorial (uncal) herniation (in cases of supratentorial mass lesion) and/or herniation of the cerebellar tonsils which are forced into the foramen magnum leading to compression of the brainstem with secondary damage and failure of the medullary respiratory centers.

From the clinical and forensic point of view, the possible occurrence of a so-called lucid or latent interval has to be mentioned. After initial unconsciousness (due to cerebral concussion), there may be a symptomless period of several hours or even days before the victim becomes comatous again because of the increased hemorrhage and, consequently, the raised intracranial pressure.

Epidural (extradural) hemorrhages are located between the skull and the underlying dura mater, which is stripped from the bone by bleeding from a torn vessel ([Figure 10](#)). Epidural hematomas have a typical disk- or lens-shaped appearance. The most common site is the temporal and the adjacent parietal region where the branches of the middle meningeal artery are easily lacerated in the course of a transecting fracture line. Since the well-adherent dura has to be avulsed from the bone, epidural hematomas more frequently originate from arterial bleeding than from venous bleeding (e.g., due to a torn dural sinus). In the great majority, an extradural hemorrhage is associated with a cranial fracture.

Figure 10 Extradural (epidural) hemorrhage in the parietotemporal area. The hematoma is located between the inner surface of the skull and the detached dura.

Figure 11 Acute subdural hemorrhage. The unilateral space-occupying lesion has slightly shifted the midline of the brain to the opposite side.

Subdural hematomas are intracranial bleedings located beneath the dura mater and above the arachnoid (**Figure 11**). Most often, the hemorrhage results from the tearing of over-stretched bridging veins that traverse the subdural space between the surface of the cerebral hemispheres and the superior sagittal sinus. Other possible sources of subdural bleeding are injuries to venous sinuses or to the cerebral parenchyma (such as cerebral contusions with concomitant laceration of the arachnoid). The subdural hemorrhage usually covers one cerebral hemisphere in a cap-like manner from the parasagittal area via the lateral surface down to the basal fossas; on a horizontal section, it appears as a sickle-shaped accumulation of blood. In contrast to epidural hematomas, subdural hemorrhages are often not associated with skull fractures; additional damage to the brain tissue may also be absent. A high

percentage of subdural bleedings are caused by acceleration or deceleration of the head, for instance, in falls when the head impacts a hard surface, and also in traffic accidents and physical child abuse (battered child and shaken baby syndrome). Apart from acute and subacute subdural hemorrhages, there are prolonged cases of hematoma formation and organization, mainly in elderly people and sometimes without a history of previous traumatization. Such chronic subdural hematomas typically consist of brown and gelatinous blood accumulations adherent to the meninges and sometimes covered with a tough membrane.

Traumatic subarachnoid bleeding may result from damage to the cortex such as brain contusion (e.g., contrecoup lesions), from penetrating injuries to the brain, and as a consequence of vessel tears within the subarachnoid space. An extensive hemorrhage on the ventral surface and around the brainstem may arise from a laceration of an artery belonging to the circle of Willis or from another great vessel (such as a torn basilar and vertebral artery).

Cerebral Injuries

'*Concussion* of the brain' is a clinical diagnosis which means a disorder of cerebral function following immediately upon a (blunt) head injury. It is usually characterized by a transient loss of consciousness (initial coma) with subsequent amnesia from the actual moment of trauma; it is often combined with retrograde amnesia and vegetative signs such as nausea and vomiting. In mere concussions, the unconsciousness lasts only for a relatively short time (<1 h) and the brain tissue does not show any evidence of structural damage. Nevertheless, even a simple cerebral concussion may be followed by the victim's death, if the head trauma is joined by interfering mechanisms (for instance, drowning or aspiration of gastric contents during unconsciousness).

Cerebral contusions are traumatic lesions of the brain frequently seen in the cortex and sometimes extending into the underlying white matter (**Figure 12**). Fresh contusion hemorrhages are mostly located on the crests of the gyri and composed of grouped streak-like or punctate blood extravasations (**Figure 13**). The cortical lesions are often covered with subarachnoid bleeding. In contrast to cerebral contusions, the term 'laceration' means a major destruction of the anatomical context (for instance, mechanical separation of the tissue due to bone fragments or penetrating bullets). In the case of survival, the contusion hemorrhages are reabsorbed and assume a yellowish-brown appearance with softening and, finally, liquefaction of the affected areas.

Due to the injuring mechanism, most cerebral contusions occur in brain regions that are directly opposite to the point of impact. This contrecoup type of contusion is classically caused by a fall on the occiput, when the moving head is suddenly decelerated with the consequence that the inlying brain is damaged due to inertia. In falls on the back of the head, the contrecoup areas of the brain (poles and undersurfaces of the frontal and temporal lobes) are subjected to an ultrashort negative pressure ('cavitation') resulting in vessel ruptures and cortical hemorrhages (**Figure 14**). On the other hand, the so-called coup contusions arise at the area of impact due to the local deformation and compression of the brain. Even

Figure 12 Contrecoup contusions of the frontal poles opposite to the point of impact (fall on the back of the head) with concomitant subarachnoid hematoma; traumatic intracerebral (subcortical) hematoma in the white matter of the right temporal lobe (in close vicinity to cerebral contusions in the overlying cortex).

Figure 13 Close-up view of a contused brain region with characteristic streak-like, densely arranged hemorrhages in the cortex (cut surface).

severe coup and contrecoup injuries are not necessarily associated with skull fractures. In victims with both coup and contrecoup lesions, the degree of contrecoup damage is usually more marked. Fracture contusions are localized in topographical correspondence to fracture lines and/or depressed fractures.

Diffuse axonal injury (DAI) is considered a consequence of shear and tensile strains from sudden acceleration/deceleration or rotational movements of the head. Overstretching of the nerve fibers in the white matter leads to axonal injury varying from temporary dysfunction to anatomical transection, the latter being followed by microscopically visible club-shaped retraction balls on the axons. The sites of predilection include

Figure 14 Contrecoup contusions on the undersurface of the frontal and temporal lobes (mostly located at the crests of the convolutions) with slight subarachnoid hemorrhage.

the corpus callosum, the parasagittal white matter, the superior peduncles, and the upper brainstem. In the course of the repair process, microglial cells proliferate in the areas of axon damage. In victims of substantial head injuries, especially after traffic accidents, DAI may be responsible for prolonged coma and a fatal outcome even in the absence of an intracranial mass lesion.

Cerebral edema is a frequent finding in significant head injuries. The formation of edema is due to an increase in the fluid content of the brain, predominantly in the white matter. Posttraumatic edema may be generalized (diffuse) or related to focal tissue damage (e.g., adjacent to an area of cerebral contusion or laceration). At autopsy, the weight of the brain is increased and the gyri are pale and flattened with shallow sulci in between. From the pathogenetic point of view, edema is attributed to a heightened vascular permeability which in turn may be worsened by additional hypoxia.

As with space-occupying lesions such as subdural or epidural hematomas, cerebral edema is a common cause of raised intracranial pressure. The enlarged volume of the edematous brain results in a displacement of cerebral tissue downwards through the midbrain opening resulting in grooving of the unci and/or hippocampal herniation. Expansion of the subtentorial brain leads to herniation of the cerebellar tonsils which are forced into the foramen magnum. Herniation with concomitant compression of the brainstem may be followed by secondary hemorrhages (localized in the midbrain and pons) and finally by lethal dysfunction of the vital centers.

Injuries of the Chest

Nonpenetrating blunt force may damage the thoracic wall and/or the chest organs. *Rib fractures* are caused by either direct or indirect violence. In the first case, a localized force is applied

and the underlying ribs are broken in the contact area; the other (indirect) type of rib fracture occurs away from the impact, mainly due to compression of the chest.

Rib fractures are frequently associated with *complications* that may be dangerous or even life threatening.

- If a victim sustains numerous fractures, the rib cage loses its rigidity so that the injured section of the chest wall will not participate in the expansion of the thorax during inspiration with the result of paradoxical respiration (*flail chest*) and concomitant hypoxia.
- Sharp, pointed ends of the rib fragments may penetrate the pleura and lacerate the lung and/or the intercostal blood vessels with consecutive bleeding into the chest cavity (*hemothorax*).
- A leak in the visceral pleura permits air to enter the pleural cavity (*pneumothorax*) so that the lung collapses, if it is not fixed to the chest wall by preexisting pleural adhesions. A valve-like leakage in the pleura leads to a so-called tension pneumothorax caused by an increasing pressure of trapped air in the pleural cavity and followed by a complete collapse of the affected lung and a shift of the mediastinum to the opposite side.
- The presence of air bubbles in the subcutis or in the mediastinum (*subcutaneous/mediastinal emphysema*) may derive from injuries of the trachea, the bronchi, the thoracic wall, or the lungs by air entering the adjacent soft tissues.

Blunt force injuries to the *lung* are mainly encountered as contusions or lacerations. A contusion is typically caused by a substantial impact on the chest with consecutive inward bending of the thoracic cage. In young victims, contusions are not necessarily accompanied by fractures of the ribs or of the sternum because of the high pliability of the juvenile thoracic cage. From the morphological point of view, a contused lung shows bruising either as a subpleural suffusion or as an intrapulmonary hemorrhage. Lacerations of the lung can result when a severe compressive or crushing force is applied to the chest so that the pulmonary tissue bursts or tears. Another possible mechanism is inward displacement of a fractured rib which impales the lung (Figure 15).

Blunt traumatization of the *heart* manifests as concussion, contusion, or myocardial rupture. In most cases, the force is directly applied to the anterior chest, which compresses or crushes the heart between the sternum and the vertebral column. Bruises of the cardiac wall may be localized in the subepicardial fatty tissue (sometimes in combination with posttraumatic coronary occlusion) or within the myocardium, which then appears dark red from interstitial hemorrhage. Lacerations of the heart are most often seen in the relatively thin right ventricle or in the atria; they are less common in the left ventricle, the papillary muscles, the cardiac valves, the interatrial, and the interventricular septum. The risk of cardiac rupture is especially high during diastole when the heart chambers are filled with blood and therefore easily burst when they are exposed to a sudden compressive force. Such injuries usually have a fatal outcome either from massive blood loss and hemorrhagic shock (if the pericardial sac is torn and the blood pours into a pleural cavity) or from cardiac tamponade (blood accumulation in the pericardial sac resulting in insufficient filling of the cardiac chambers and impaired forward circulation).

Figure 15 Serial rib fractures of the right hemithorax with concomitant laceration of the lung.

Traumatic aortic ruptures typically occur in vehicular accidents and in falls from a height. The most important mechanism is sudden deceleration, possibly in combination with compression and/or shearing. Traction forces tear the aorta transversely at two sites of predisposition: in the descending part of its arcus (near the attachment of the ligamentum arteriosum) (Figure 16) or immediately above the cusps of the aortic valve. Other locations (for instance, in association with a dislocated vertebral fracture) are rather rare. The laceration of the aorta may occur as either a complete or a partial transection. In the latter case, the outer layers of the vascular wall are not damaged; the intimal tears are often multiple, semicircular, and parallel (so-called ladder-rung tears). If the trauma is survived at least for a short time, a parietal thrombosis or a posttraumatic aneurysm may follow as a secondary complication.

Abdominal Injuries

Blunt-force injuries of the abdomen are frequently seen in traffic and work accidents, in child and spouse abuse, in other criminal assaults (with kicking, stamping, and punching), as well as in suicidal falls from heights. The abdominal organs most vulnerable to blunt trauma are the solid liver and spleen on the one side and the mesentery on the other. Concomitant external signs of blunt traumatization such as contusions or abrasions are by no means obligatory. Substantial injuries to the liver, the spleen, and the mesentery have always to be regarded as life-threatening and potentially fatal, especially in cases without rapid surgical treatment. The main reason is internal bleeding into the peritoneal cavity from lacerations (Figures 17 and 18). Ruptures of the liver and spleen can be classified as either transcapsular or subcapsular lacerations. In the first case, both capsule and parenchyma are injured so that the blood instantaneously pours into the

Figure 16 Transection of the aorta in the distal part of the arch (deceleration injury).

peritoneal cavity. The second type of laceration is characterized by the initial formation of a subcapsular hematoma which expands continuously and possibly causes a delayed rupture when the covering capsule tears due to overstretching (mostly several hours or even days after the trauma).

The stomach and the intestine are less susceptible to blunt traumatization than the parenchymatous abdominal organs. The hollow viscera are more likely to rupture, if they are filled with food or fluid. Another reason why the intestine or stomach might be prone to damage is squeezing of the organs between the indented abdominal wall and the lumbar vertebrae. Fatal outcomes from contusions or lacerations of the gastrointestinal tract are usually due to diffuse peritonitis.

Renal injuries are a relatively rare source of severe bleeding as the kidneys are located deep behind the peritoneum. Nevertheless, they can be ruptured by a heavy impact to the loin (for instance, in traffic accidents or assaults).

Although the empty urinary bladder is placed within the pelvis, when filled it moves upwards and is therefore exposed to blunt traumatization of the lower abdomen. Consequently, rupture of the empty bladder is expected to be extraperitoneal and accompanied with pelvic fractures, whereas a bladder distended with urine may rupture into the peritoneal cavity.

Blunt traumatization of a pregnant uterus is a possible cause of fetal death, mostly due to separation or rupture of the placenta.

Injuries to the Extremities

Besides injuries to the skin and the subcutaneous layer (see above), other anatomical structures such as the muscles,

Figure 17 Multiple transcapsular lacerations of the liver.

Figure 18 Laceration of the spleen.

the bones, and the joints may be involved in blunt force trauma. Extensive crushing of the soft tissues, the formation of blood-filled cavities, comminuted fractures, and severance of large vessels are common findings in victims of automobile-pedestrian accidents. Internal bleeding (from closed injuries) and external bleeding (from traumatic amputation, severe avulsive wounds, and compound fractures) are important factors contributing to hemorrhagic shock. Another sequel to blunt trauma is pulmonary and systemic fat embolism (caused by globules of fat, usually subsequent to fractures or damage of fatty tissues). In cases of prolonged survival, intercurrent infection and pulmonary embolism (originating from posttraumatic venous thrombosis) are dangerous and often fatal complications of an originally nonlethal injury.

Burns and Scalds

M Bohnert, University of Würzburg, Würzburg, Germany

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The possible findings in burned bodies cover a broad spectrum, ranging from minor, local, superficial burns of the skin to calcined skeletal remains without any soft tissue left and total incineration. The extent of the tissue changes depends on the temperature actually applied to the body, the time for which it is applied, the kind of transmission of the heat to the body, and other prevailing conditions. In most cases, the heat acts on the body beyond death. Consequently, the changes found are largely of postmortem origin.

The forensic investigation of deaths related to a fire is important to determine the manner and cause of death, the vitality of the findings, and the identity of the victim. In some cases, questions concerning the dynamics and the duration of the fire have also to be answered.

External Findings

Among the externally discernible changes, the various stages of skin burns, the results of tissue shrinkage, and the consumption by the fire are the dominant features. In most fire deaths, the body was exposed postmortem to temperatures of several hundred degrees Celsius for at least some minutes, often by direct contact with the flames. Although destruction may be very extensive, in most of the cases, the organs of the thorax and abdomen can usually still be assessed quite well and body fluids as well as tissue samples can be obtained for further investigations.

Burns

Skin burns are categorized into four degrees with each degree characterizing a certain depth of the skin lesion. The categories are (degree 1) superficial burns, (degree 2a) superficial partial-thickness burns associated with necrosis of the upper layers of the epidermis, (degree 2b) deep partial-thickness burns associated with necrosis of the entire thickness of the epidermis, (degree 3) full-thickness burns with necrosis involving the dermis as well, and (degree 4) charring in which the heat lesion reaches deeper soft-tissue layers. First-degree burns are characterized by a reddening of the skin. As a postmortem residue, a red margin may occasionally be observed. Second-degree burns are characterized by fluid-filled skin blisters. Second-degree burns of the palms of the hands and the soles of the feet appear as whitish discolorations of the epidermis associated with swelling, wrinkling, and vesicular detachment up to glove-like peeling. The findings resemble the so-called washer-woman's skin, as it is seen after prolonged exposure to a moist environment. The skin in third-degree burns is firm and discolored brown.

Heat changes of the hair occur at temperatures above about 150 °C. This can be used to differentiate between burns and

scalds or to indicate the approximate temperature reached by the skin in smoldering fires. The hair gets frizzy and brittle and assumes a fox-red or a dark-brown to black color. Temperatures of about 200 °C lead to the formation of gas bubbles in the shaft. At 240 °C, the hair becomes frizzy due to the melting of the hair keratins. Above 300 °C, charring occurs.

The distribution of burn injuries is seldom evenly spread and depends on various conditions. Especially, tight-fitting clothes can protect the underlying skin from burns for a long time. In cases of suicidal self-incineration using fire accelerants, burns may be absent from the feet and lower legs if the incineration took place while the body was in an upright position. In burns caused by low heat, deep, anatomically circumscribed signs of consumption by the fire may occur. These are formed when the fire is maintained according to the wick principle: In those parts of the body where the skin has burned away, liquefied subcutaneous fatty tissue leaks out and maintains the fire.

Shrinkage of Tissue

The reasons why the tissue shrinks are the loss of fluid and the degradation of the muscles and tendons caused by the heat. Externally, it is characterized by tightening of the skin, splitting of the skin, protrusion of the tongue from the open mouth, petechial hemorrhages in the region of the neck and head, and the so-called pugilistic attitude.

The typical posture of charred bodies is called the pugilistic or boxer's attitude with the arms being abducted in the shoulder joint and flexed in the elbow joint and the legs being abducted in the hip joint and flexed in the hip and knee joint. The flexion of the joints of the extremities is due to the predominance of the flexor muscles. This may even result in dislocation, most often recognizable at the wrists.

Splitting of the skin is a frequently observed phenomenon in charred bodies. It is very rare in burns of minor severity. If it appears in such cases, prolonged exposure to the heat has to be assumed. The splits have sharp edges that can be approximated, are often linear, but occasionally also angled. In most cases, they reach the subcutaneous fatty tissue, and sometimes also the outer muscle layers. In this context, little attention is paid to the fact that the tissue exposed in the depth of the splits is usually unburned and often not even sooted. Most likely, the splits form during the cooling of the body.

Protrusion of the tongue from the open mouth is due to the heat-related shrinkage of the soft tissue of the neck. In the presence of severe burns on the neck and/or thorax, petechial hemorrhages may occasionally be found in the lids and conjunctivae. For their formation, congestion due to the shrinkage of the soft tissue of the neck by heat or heat rigidity of the thorax while the circulation is still intact is discussed. So, petechial hemorrhages in the region of the neck and head would have to be regarded as a vital sign.

Consumption by Fire

The question as to what extent the level of charring in a burned body allows one to draw conclusions regarding the duration of the fire is rarely asked. In the literature, there are few reports on this topic, most of which refer to observations made during cremations. These studies showed that the course of events follows a fixed chronological order. Thirty minutes after the fire has been in full progress, all body cavities are exposed and the distal portions of the extremities are amputated. The exposed bones show signs of calcination. After a minimum of 50 min and a maximum of 80 min, the internal organs are largely incinerated and the burned torso breaks apart. However, when applying the findings of the cremations to real fire deaths, one should take into consideration that these are usually not exposed to a constant temperature level for a long period of time; a fire develops in several stages and it will often not be possible to reconstruct the temperatures reached in these individual stages.

Internal Findings

The internal findings in fire deaths are the result of a fixation of the tissue by the heat, processes of shrinking, thermal changes of the content and distribution of tissue fluids, and a rising gas pressure in hollow spaces. After the fire has opened the body cavities, direct burns occur on the internal surfaces as well. The loss of fluid and, after exposure of the body cavities, the direct effect of the heat cause shrinking of the internal organs, which become firm, hardened, and cooked by the heat (so-called 'puppet organs'). The surface of the organs becomes increasingly bosselated and is reduced to a sponge-like residual structure in the end. The tissue is meanwhile completely desiccated and disintegrates into ash at the slightest touch.

Respiratory Tract

The respiratory tract is the most important organ system for the diagnosis of vitality. Where fire fumes were inhaled, deposits of soot particles will be found. Edema, mucosal bleeding, and patchy or vesicular detachment of the mucosa in the nose, mouth, pharynx, larynx, trachea, and bronchi may be indicative of an inhalation of hot gases. Often, increased secretion of mucus is observed in the air passages. This may be interpreted as an attempt to cool the surfaces of the air passages and thus as a sign of vitality, if other causes for the secretion of mucus (bronchial asthma and catarrhal bronchitis) have been ruled out. Damage caused to the respiratory tract by dry heat is limited more to the upper portions. The inhaled hot air is sufficiently cooled down by the mucosa of the airways so that after exposure to a 'normal fire,' hardly any changes are found in the medium and small bronchi.

Vessels

Intensive red discoloration of the intima of the vessels can be regularly observed in fire victims. This finding is the result of hemolysis occurring at temperatures above 52 °C. Even at 48 °C, erythrocytes begin to dissolve. If the circulation is still

intact, the erythrocyte fragments ('fragmentocytes') can be demonstrated microscopically in other organs also, which has to be interpreted as a sign of vitality.

Gastrointestinal Tract

The abdominal wall protects the abdominal organs from direct damage by the flames for a relatively long period of time. However, as a result of the heating of the body, the tissue fluids boil away and the pressure inside the hollow organs and the abdominal cavity builds up, which often leads to the rupture of the abdominal wall and the prolapse of intestinal loops. Consumption of the abdominal wall by the fire further promotes the rupture. In rare cases, heat-related ruptures of the gastrointestinal organs are found, before they were directly exposed to the fire.

Bones

The skeleton is damaged by the fire, but it is not consumed completely. Even if it is exposed to a fire with high temperatures over a long period of time, there will usually still be remains to allow macroscopic assessment and successful determination of the species, the body measurements, and the sex as well as to identify skeletal anomalies and the presence of possible injuries.

At temperatures above 700 °C, complete combustion of the organic substances with incineration and recrystallization of the inorganic matter occurs, which is called 'calcination.' The bones are grayish-white, desiccated, and disintegrate easily. The surface shows characteristic tears partly reflecting the course of the trabeculae, but often also being irregular in structure.

In charred or calcined bones, a minor mechanical strain may be enough to cause fractures. Especially in fractures localized within charred bone areas, the possibility of artifacts should be considered. But several authors have stressed expressly that injuries sustained during life can be demonstrated even on charred or calcined bones.

In the assessment, special attention must be paid to the bony skullcap. In about 33% of all fire deaths, the skullcap is partially destroyed and the interior of the skull is exposed, which makes assessment even more difficult. Isolated fractures of the external table are seen especially in cases where a defined area of the skullcap was in direct contact with the flames. Prolonged exposure to heat causes fractures of the entire thickness of the skullcap, with occasional bursting of the sutures of the skull. The tears in the skullcap caused by heat may radiate from a center, but can sometimes also be elliptic or circular in shape or resemble a spider's web fracture. In rare cases, round or oval bone fragments may burst outward. Distinction of this finding from a gunshot injury may be difficult.

Cranial Cavity and Brain

A frequent finding is the epidural heat hematoma. It is not a vital sign, but a postmortem effect due to the shift of fluid from the diploe and the venous sinuses when the skullcap is in direct contact with the flames. Accordingly, charring of the bony skull is usually found above the site of the heat hematoma. It is dry,

crumbly, and of brick-red color. Occasionally, it may be surrounded by fat and in rare cases, accumulations of fat without extravasations of blood can also be found in the epidural space. Apart from that, the hematoma is sometimes found to be interspersed with brain tissue when the dura mater is torn due to shrinkage by heat.

Postmortem extravasates of blood may occur in all cavities of the skull including the ventricles of the brain. But hemorrhages can be found in the brain tissue itself as a result of the shrinkage of tissue with laceration of small blood vessels. In these cases, distinction between postmortem and vital hemorrhages can be particularly difficult.

When the skullcap is intact, the brain of fire victims is often shrunken and of a hardened consistency with filled sulci on the surface. Histologically, condensation of the vessels and widening of the Virchow–Robinson spaces have been described. Again, this finding may be explained as the result of a loss of fluid and does not prove a vital thermal damage to the tissue.

Toxicology

In fire victims, the concentrations of carbon monoxide hemoglobin (CO-Hb), methemoglobin (Met-Hb), and cyanide (CN) should be routinely determined in the corpse blood as part of the toxicological investigations. Concentrations of more than 10% CO-Hb and more than 0.2 mg l⁻¹ CN in the blood suggest that fire fumes were inhaled and are to be considered as signs of vitality. A positive result for Met-Hb indicates that nitrous gases formed during the fire and were inhaled. As the sole cause of death, elevated concentrations of CO-Hb and CN have to be considered especially in victims showing only minor heat changes on the body. Blood concentrations of more than 50% CO-Hb and 2.6 mg l⁻¹ CN are considered as lethal.

In deaths following flash fires, pulmonary tissue should also be kept as evidence to demonstrate the use of fire accelerants. As these substances are volatile, it is advisable to store the samples in airtight containers and to investigate them rapidly by means of headspace capillary GC–MS. A positive result for fire accelerants in the pulmonary tissue is also regarded as a sign of vitality.

Histology

Histological examination of the respiratory tract is especially valuable to demonstrate changes due to the inhalation of hot gases. However, it should be remembered in this context that certain findings, for example, nucleic elongation and palisade arrangement in the epithelium of the respiratory tract, may also be due to postmortem effects of heat on the body. On the other hand, other findings such as hyperemia and edema of the mucosa of the respiratory passages as well as interstitial and intraalveolar pulmonary edema are unspecific. Detachment of the mucosa from the epiglottis, the trachea, and the bronchi may also be due to autolysis and decomposition, although rarely in the vesicular form, characteristic of thermal effects. The histological parameters should also be assessed only in context. In our experience, the combination of pseudogoblet

cells, increased secretion of mucus, and vesicular detachment of the epithelium is highly indicative of vital effects of heat on the respiratory system. Histological findings of the pulmonary tissue in cases of rapid death may be acute congestion, interstitial and sectional intraalveolar pulmonary edema, and acute emphysema, as well as microthrombi.

Diagnosis of Vitality

The signs of a vital exposure to the fire are summarized in **Table 1**. External signs that the body was exposed to heat when the victim was still alive may be the absence of burns and/or soot deposits in the corners of the eyes (so-called crow’s feet) and incompletely singed eyelashes, which result from squinting the eyes. However, these findings are usually discernible only if the body was not or was only slightly consumed by the fire. As this is rare in deaths due to heat exposure, the internal findings are much more important than the external findings.

The most important constellation of findings to prove that the victim was alive during a fire is the combination of a CO-Hb concentration above 10% and soot deposits in the respiratory tract, the esophagus, and the stomach. In fact, these parameters show only whether the victim was exposed to *fire fumes* while alive; they are not indicative of vital *heat* exposure. Consequences of an inhalation of hot gases may be edematous swelling and vesicular or patchy detachment of the mucosa in the pharynx, the larynx, and/or the upper section of the esophagus.

Although there is a certain relation between the vitality parameters of soot aspiration and CO-Hb, there is no reliable

Table 1 Signs of vitality after exposure to fire fumes versus heat

<i>Exposure to fire fumes</i>	<i>Exposure to heat</i>
<i>Macroscopic findings</i>	
Soot deposits in the airways	Crow’s feet, incompletely singed eyelashes
Soot deposits in the esophagus	Skin blisters
Soot deposits in the stomach	Vesicular/patchy detachment of the pharyngeal mucosa or epiglottis Edematous swelling of the epiglottis Vesicular/patchy detachment of the upper esophageal mucosa
<i>Histological findings</i>	
Soot deposits in trachea and bronchi	Vesicular detachment of the tracheal and bronchial mucosa Pseudogoblet cells Massive secretion of mucus Nucleic elongation and palisade arrangement of the mucosal epithelium in trachea and bronchi Hyperemia and edema of the tracheal and bronchial mucosa
<i>Toxicological findings</i>	
CO-Hb concentration >10%	
Cyanide concentration >0.2 ng ml ⁻¹	

correlation. Deposits of soot in the airways should never lead to the premature conclusion that the victim died of intoxication by fire fumes. Soot particles may, under certain circumstances, occur in the respiratory tract also if burning was exclusively postmortem. On the other hand, the absence of soot in the respiratory tract does not allow to draw the conclusion that exposure to the fire occurred postmortem. Signs of vitality may be partly absent in cases of undoubtedly vital burning. The significance of one vitality parameter alone is therefore limited.

Determination of the Cause of Death

The issues of vitality and cause of death are closely linked. For example, a high CO-Hb concentration in corpse blood supplies information regarding the cause of both the death and vitality. Apart from the signs of vitality, the absence of other causes of death is an essential condition for the conclusion that death was due to the fire. The diagnosis of a fire to cover up a homicide requires the presence of fatal injuries inflicted by another person *and* the absence of the classical parameters of vitality.

The presence of mechanical lesions or severe pathological findings together with (seemingly) absent vital parameters may cause diagnostic problems. While in the presence of potentially fatal injuries (e.g., polytrauma following car accidents) perimortal burning has to be discussed, differentiation between peracute death due to the effects of heat and purely postmortem burning may be very difficult. In cases of this type, the CO-Hb concentrations in the corpse blood may be below 10%, the oral, pharyngeal, and laryngeal mucosa may show no heat damage, and there may be no soot aspiration. The most likely pathophysiological mechanism is a fulminant shock. However, in some cases, the questions regarding the cause of death and the vitality cannot be answered definitely.

Scalds

Scalds are the result of the effect of moist heat, usually hot water and/or steam, while scalding by other hot liquids, especially hot oil, is a comparatively rare picture to be examined in forensic practice. As the thermal conductivity of water and steam is much higher, they produce worse injuries than dry heat even after short exposure, as from the very beginning the actual skin temperature is considerably higher with moist heat and moist heat penetrates to deeper layers of the tissue much better than dry heat.

An actual skin temperature of 44 °C is regarded as the lowest temperature needed to cause damage to the skin; at this temperature, a second to third-degree scald would be reached after an exposure time of 6 h. Between 44 and 51 °C, a temperature increase of 1 °C reduces the exposure time needed for a certain degree of skin injury by half. Above 51 °C, there is no convective heat transport via the skin capillaries anymore and the heat penetrates into the deeper tissue layers.

External Findings

Typical for the effect of moist heat is a uniform injury pattern of all the affected skin areas with sharply demarcated edges. Pouring a hot liquid over the skin may produce a streak-like trickle pattern. Scalds due to immersion are characterized by a straight, horizontal burn pattern corresponding to the level of the liquid. With tight-fitting clothes, the underlying skin areas may often be spared from scalding. As the temperatures applied by moist heat are usually lower than those of dry heat (water boils at 100 °C), moist heat does not produce fourth-degree skin burns (charring), heat-related exposures of body cavities, or amputations.

Internal Findings

The internal findings are unspecific. They are consequences of the shock associated with scalding which can also be regarded as the cause of death. If hot steam is inhaled, the temperature hardly declines along the air passages, so that a direct thermal damage may occur even in the peripheral parts of the respiratory tract. For differentiation between hot steam and dry air, the so-called 'pleura sign' can be used at autopsy. If hot steam was inhaled, the parietal pleura is reddened, whereas the costodiaphragmatic angles are pale. In deaths caused by the effects of dry heat, this sign is absent even if the circumstances suggest a fire with high temperatures.

Asphyctic Deaths – Overview and Pathophysiology

CM Milroy, University of Ottawa, Ottawa, ON, Canada

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Sphygmomanometer Equipment to measure blood pressure.

Valsalva maneuver Forceful exhalation against a closed upper airway.

Introduction

Asphyxia is a very commonly used term in medicine, and particularly forensic medicine, though the characteristics that are used to diagnose asphyxia are poorly defined and often absent in cases of classic 'asphyxia.' The term asphyxia derives from ancient Greek and etymologically means absence of the pulse (σφυγμός – sphygmós). (Sphygmomanometer has the same origin.) However, it has come to mean deaths associated with deprivation of oxygen. While most deaths will ultimately result by starvation of oxygen to vital organs, 'asphyxial' deaths are separately classified in Forensic Medicine. Different texts have classified asphyxial deaths into different ways, so there is a lack of uniformity in definition.

Signs of Asphyxia

Asphyxial deaths have been associated with specific pathological findings. Classically, the literature has reported five so-called signs of asphyxia as follows:

1. Congestion
2. Cyanosis
3. Fluidity of blood
4. Dilatation of the right side of the heart
5. Petechiae

None of these signs is specific and is so commonly found in nonasphyxial deaths and absent in asphyxial deaths that they have been referred to by Lester Adelson in a memorable quote as the obsolete quintet.

Of these signs, congestion and cyanosis are almost universal findings to a greater or lesser degree in most autopsies. Fluidity of blood has long been shown to correlate with the rapidity of death rather than whether there has been deprivation of oxygen or dilation of the right side of the heart is a nonspecific and subjective finding.

Of Lester Adelson's obsolete quintet, petechiae merit some discussion as the mechanism of their causation and their significance has been more debated. Petechiae are pinhead-sized hemorrhages most commonly associated with compression of the neck but may be seen in natural deaths including cardiac disease. Petechial bruising describes a separate type of appearance to a bruise. Other causes of petechiae include clotting disorders, coughing, retching, and vomiting. They may be seen in internal organs, typically in thoracic organs. Over-reliance on

these findings has led to inappropriate diagnoses of deaths from asphyxia.

Petechiae have been stated to be associated with raised intravascular pressure, hypoxia, and raised carbon dioxide. Of these mechanisms, only raised intravascular pressure has any scientific evidence to support it, in the absence of a bleeding diathesis. Raised intravascular pressure accounts for why they are seen in compression of the neck, coughing, retching, and similar acts that raise venous pressure, but not, for example, in most smothering deaths or suffocation. In compression of the neck, one of the common scenarios that petechiae are seen in, they result from obstruction of the venous return with continued arterial pressure, resulting in engorgement of the vascular system and rupture of venules resulting in petechiae appearing. Although petechiae are sometimes said to arise from rupture of capillaries, it has been pointed out that these structures are too small to result in macroscopically visible hemorrhage. The most common places to observe petechiae are in the conjunctivae, in the external eyelids, on facial skin, behind the ears, and on the mucosal surface of the oral cavity. Petechiae are invariably seen on the inside of the scalp following reflection at autopsy. These subscalp petechiae are an artifact of dissection and are not diagnostic of anything. In deaths where there has been a head down postmortem position, the scalp, face, and neck can become very congested, and petechiae and confluent areas of bleeding may be seen. Artefactual bleeding may be seen in the neck, even with careful dissection after draining the blood.

Mechanisms of Asphyxia

In classifying deaths from asphyxia, rather than referring to deaths from asphyxia, a more accurate approach is one where the mechanism of the production of asphyxia is described.

The deaths that fall into the category of 'asphyxia' deaths can be broadly categorized as follows:

1. Suffocation (breathing in a nonviable environment)
2. The mechanical asphyxias
 - (a) Smothering
 - (b) Plastic bag asphyxia
 - (c) Choking
 - (d) Compression of the neck
 - (e) Traumatic asphyxia
 - (f) Positional/restraint asphyxia
 - (g) Drowning

- (h) Autoerotic sexual asphyxia
 - (i) The 'choking game'
3. Chemical 'asphyxiants.'

Suffocation

The term suffocation is best reserved for cases where there has been inhalation of a vitiated atmosphere. These deaths can occur when a person enters an atmosphere where there is inadequate oxygen or where the oxygen gets used up. Typical examples include mines and silos, where there has been a reduction in environmental oxygen and a buildup of carbon dioxide. Collapse can be very rapid and coworkers may die when they enter the same atmosphere in an attempt to rescue them. Characteristically asphyxial signs are absent. One case seen by the author involved three men in the cable room of a ship where the anchor was stored. These rooms typically have low oxygen levels as the iron in the cable rusts and oxygen is used up in making iron oxide. A worker entered the room without appropriate breathing apparatus and collapsed. His two colleagues attempting to rescue him without breathing apparatus also collapsed and all three died. Subsequent analysis of the oxygen level in the room showed it to be reduced. This illustrates that the autopsy must be interpreted with other information, as the autopsies did not disclose the cause of death.

Another scenario encountered is when people become trapped in fridges or are placed in a trunk or similar closed environment. As the oxygen is used up and carbon monoxide builds up, death will occur.

Smothering

The term smothering should be used when an external object has been used to obstruct the upper airway. This obstructs normal respiration. It is often achieved with soft material and when autopsy signs are absent. If duct tape or similar material has been used and removed, there may be adhesive material still present around the mouth, which can give a clue to the previous presence of the tape and other injuries possibly being present.

Plastic Bag Asphyxia

Plastic bag asphyxia is a specific form of obstruction of the upper airway. Asphyxial signs are typically absent. It may also be accompanied by the administration of the irrespirable gas helium, which has been recommended as a method of suicide by certain euthanasia supporters.

Choking

Choking is a term best used when there is obstruction of the internal airway by food or other obstructing material, though it has been used for external compression of the neck. The 'choking game' is described below. It is commonly encountered in

intoxicated people or in patients with neurological disorders that prevent adequate swallowing. Occasionally, cases are encountered where material is forced into the mouth and airway, either by an assailant or by a self-infliction. Such acts may be encountered in psychiatrically disordered patients and people determined to commit suicide, such as by stuffing a sock or tissue paper into the throat.

Compression of the Neck

Compression of the neck is a broad category of actions that result in obstruction of the vasculature and airway. These deaths are classified and described in the sections below.

Hanging

There is a compression of the neck by suspension by a ligature. Hanging can be separated into short-drop and long-drop suspension. The latter, most typified by judicial execution, is meant to result in fracture of the neck rather than compression of the vasculature and airway, which occurs in 'short-drop' suspension. Long-drop hangings may be seen in suicides, such as hangings off bridges and similar structures. If the drop is of sufficient length, decapitation may occur.

Hanging may be achieved even though a significant part of the victim's body is on the ground, as there is sufficient weight even in the head to achieve vascular compression. There is characteristically a parchmented ligature mark, but where there is a broad ligature, such as a sheet, the ligature mark can be subtle or absent. In compression with full suspension, petechiae are typically absent and the face appears pale. In these cases, there is complete compression of the carotid arteries with no blood flowing above the level of the compressing force. In contrast, in partial suspension, petechiae and congestion above the level of the ligature are more commonly encountered.

Hanging is typically suicidal but may occur by accident or rarely be homicidal. With homicidal hanging, either the victim is incapacitated or there is a significant disparity in strength between assailant(s) and victim. Rarely homicidal hanging has been reported through subterfuge. Internal findings may be absent in hanging or include bruising of the strap muscles and fracturing of the hyoid bone and laryngeal cartilages.

Ligature Strangulation

There is a compression of the neck without suspension. Petechiae more commonly occur with ligature strangulation than hanging as the compressive force is typically slower, allowing congestion of vessels to occur. External signs of the ligature may be subtle where the ligature is broad. This is commonly homicidal but may occur in suicides or by accident. Where a low suspension hanging has occurred, differentiating ligature strangulation may be extremely difficult, where the person has been cut down and the ligature removed. Where a stick or similar object is placed under the ligature and twisted to constrict the ligature, the mechanism is referred to a Spanish windlass. Garroting is a special form of ligature strangulation

where the intention is to fracture the neck. It was used as a form of judicial execution.

Manual Strangulation

This is also called throttling and occurs when the hands (hence manual) are used to compress the neck. External marks of violence can be quite subtle, but usually finger pressure bruises and abrasions from fingernails are seen. The abrasions may be from the victim's own fingernails, where they have attempted to remove the assailants compressing hands. Internally, there is typically bruising in the strap muscles. Damage to the hyoid bone and laryngeal cartilages is more common in manual strangulation, but depends on age, with younger people having elastic cartilage. Fractures are invariably present in people over 50 years of age.

Palmar Strangulation

Polson describes a method of neck compression where the accused denied gripping the neck but stated that he had placed one palm on the mouth and another on the front of the neck, so that pressure is over the larynx. The victim, a 52-year-old woman, had fractures of both superior horns and bruising in the neck. Polson was able to reproduce the fractures on cadavers.

Neck Holds

There are two basic neck holds, 'choke' holds and the carotid sleeper. With the carotid sleeper, when correctly applied, the neck is held in the crook of the arm and then the arm is compressed so that the carotid arteries are obstructed. When used in law enforcement hold and martial arts, once the person has become unconscious, the hold is released. If the hold is continued then death will result from a lack of blood supply to the brain. The airway is supposed to be maintained with this hold. The term mugging was originally applied to this hold, though it has become a term used for any street robbery. This is in contrast to the 'choke' hold or bar hold, where either the forearm or a similar shaped object such as a police truncheon is placed across the neck and then forced onto the neck. This causes compression of the airway with collapse of the trachea rather than just obstruction of the carotid arteries.

Traumatic (Crush) Asphyxia

Traumatic asphyxia, also known as crush asphyxia, occurs when there is pressure placed on the chest so that normal respiration cannot occur. Traumatic asphyxia may occur when there is crushing in a crowd, as has happened in a number of sports stadia disasters, such as in Hillsborough, Sheffield, UK in 1989 in which 96 people lost their lives. Ninety four died on the day and only 14 of the victims arrived in hospital.

Individual cases of traumatic asphyxia may be encountered in such scenarios as vehicular collisions, collapse of trenches, and industrial equipment incidents.

At autopsy, there is typically prominent congestion of the upper half of the body with prominent petechiae. Other

injuries indicating the site of compression may be present. These deaths often have the most florid congestion and petechiae of all the asphyxial death.

Burking

Burking is a special type of asphyxial death derived from the activities of the early nineteenth century body snatchers Burke and Hare. Burke and Hare killed 16 victims and sold the bodies for anatomical dissection. Hare turned King's evidence (state immunity) and gave a description of the method of killing. He stated that Burke 'got stridelegs on the top of the woman on the floor, and she cried out a little, and he kept in her breath. ... He pressed down her head with his breast. ... He put one hand under the nose and the other under the chin, under her mouth. ...' External injury was absent. It is noteworthy that Christison stated one of the victims – 'presented the signs of asphyxia – vague enough in general and in this instance particularly so, because the murderers left no external local marks. ...' illustrating the problem of identifying many deaths classified as asphyxia.

Positional and Restraint Asphyxia

The term positional asphyxia has been used in two main ways in Forensic Medicine. First, it has been used in people who manage to get themselves into a position where they then cannot properly breathe. This may be because they are intoxicated or are otherwise incapacitated, such as from a head injury, and so cannot extricate themselves from the position.

The second usage has been in deaths associated with restraint. In these often controversial cases, it has been argued that these deaths are not from the restraint/position the person has been placed in, but the underlying condition that caused the person to become involved in the struggle. These people are typically intoxicated with cocaine or have an underlying major psychiatric disorder and die following a struggle with law enforcement or health care personnel. Research on healthy volunteers has shown that placing someone on their back and compressing the back with a weight is equivalent to a person placing their knee on the back does not significantly alter their clinical respiratory function. It is thus argued that the position these people are placed in does not cause their death. One hypothesis made is that these people are dying of restraint asphyxia. One proposed mechanism of death has been catecholamine excess causing cardiac arrhythmia, possibly combined with a degree of deoxygenation during the struggle. Another evolving possibility is that these are vulnerable people with associated underlying disorders such as cardiac conduction and long-QT syndrome. Whether these deaths are true, asphyxia deaths remains disputed. The science of these deaths is evolving and many of these deaths are likely multifactorial.

Drowning

Drowning can be considered a form of an asphyxial death, though it is separated because of the special circumstances.

However, in wet drowning, there is obstruction of normal respiration by liquid in the airway. Dry drowning, where there is no evidence of fluid present in the airway, has been proposed to be due to a reflex cardiac arrest or possibly by laryngeal spasm.

Autoerotic Sexual Asphyxia

It is well recognized that some deaths involve sexual activity and restriction of oxygen supply. The victims are almost exclusively male. The mechanisms of production of asphyxia encompass those described above but with the intention of producing temporary asphyxia for sexual pleasure and not death. They are commonly hangings, but other mechanisms may occur, including the use of plastic bags and combined with drug or volatile substance use. Bizarre mechanisms are occasionally encountered and knowledge of the possibility of self-inflicted injury may enlighten the investigation. Sexual asphyxia produced by couples may also occur.

The Choking Game

As well as autoerotic asphyxia, induced asphyxia for nonsexual pleasure may be seen and is known as the 'choking game.' This is most commonly seen in adolescents. The mechanism of production of asphyxia most often involves compression of the neck or compression of the chest. Subjects may also hyperventilate and then perform the Valsalva maneuver.

Chemical Asphyxiants

There are two main chemical asphyxiants encountered in forensic medicine, such as carbon monoxide poisoning and cyanide. These two substances may be encountered together in fires or as separate poisons. Their mechanism of depriving cells of oxygen is different. Carbon monoxide combines with hemoglobin to produce carboxyhemoglobin and prevents oxygen reaching cells. In comparison, cyanide stops cellular metabolism by interfering with cytochrome *c* oxidase. Both are associated with lividity being redder than normal. This is because of the formation of carboxyhemoglobin in carbon monoxide, which imparts a cherry red appearance to blood. With

cyanide, there is a failure to use up oxygen, so blood remains oxygenated. While cyanide and hemoglobin combine to form a compound *in vivo*, which has a red color, little is produced in fatal cyanide poisoning. A similar reddening of the skin can be seen in bodies that have been refrigerated and where no chemical asphyxiant has been administered. Hydrogen sulfide is another chemical asphyxiant, which may be encountered. It has the unusual feature of turning the brain green. It has been used in suicides by combining polysulfide-containing fungicides with a strong acid.

Conclusions

Deaths from deprivation of oxygen are one of the main mechanisms of death in forensic medicine. There are no specific findings of asphyxia at autopsy. While terminology may vary slightly, as long as the proposed mechanism of production of the deprivation is explained, then confusion should be eliminated.

Glossary

Asphyxia A condition of severely deficient supply of oxygen to the body, resulting in hypoxia and hypercapnia

Petechiae Punctiform bleeding caused by an acute rise in venous pressure

Hypercapnia A condition where there is too much carbondioxide in the blood

Hypoxia A pathological condition in which the body is deprived of an adequate oxygen supply

Strangulation External pressure applied to the neck, mostly by using hands or a ligature

The term 'strangulation' refers to asphyxia as a result of external pressure on the neck. There are three principal forms of strangulation: hanging, strangulation by ligature, and manual strangulation. All of them deprive the body of oxygen and typically impair the blood supply to the brain.

The neck contains the anatomical structures ensuring the transport of respiratory gases and blood: larynx and trachea, the arterial blood vessels (which transport oxygen-rich blood to the head and especially the brain), and the large cervical veins (through which oxygen-poor blood flows back to the heart). Compression of the cervical soft tissues can occlude the respiratory tract and/or the blood vessels. The pathophysiological consequences depend on the localization, kind, duration, and intensity of the pressure. In the following, the impairing mechanisms of strangulation, its subclassifications, and the respective morphological findings are discussed.

Airway Occlusion

Ventilation can be interrupted in different ways: First, direct pressure on the airways can reduce their width, making the passage of air more difficult. If the pressure forces displace the cervical soft tissue upward and backward, this causes occlusion ('tamponade') of the upper respiratory tract, as the root of the tongue is pressed against the palate and the posterior wall of the pharynx. The force needed for airway occlusion is higher than that required for the occlusion of blood vessels.

Compression of the Cervical Arteries

The brain is supplied with oxygen-rich blood via the carotid and the vertebral arteries. The latter are well protected in the depth of dorsal neck structures as they run along the spine; they enter the cranial cavity through the foramen magnum of the occipital bone. The carotid arteries are localized on either side of the larynx and surrounded by soft tissue. Occlusion of the carotid arteries requires a slightly higher pressure than occlusion of the thin-walled jugular veins.

The duration of the neck compression is also of crucial importance. When the carotid arteries are occluded, the victim becomes unconscious within seconds, while after isolated interruption of the airways, consciousness and the ability to act

may be retained for more than a minute under certain circumstances. For a limited period of time, the impairment of brain functions is still reversible. If total occlusion of the blood and oxygen supply continues, irreversible damage with a fatal outcome is to be expected within 3–5 min.

Occlusion of the Neck Veins

Comparatively low pressure forces are required to impair the blood flow in the cervical veins. From the head, blood is transported back to the trunk via the paired jugular and the vertebral veins. The former run between the cervical muscles and are wrapped by soft tissue, the latter are well protected in the depth and descend along the spine.

Although there are many connections between the cervical veins, sudden occlusion, as it occurs in strangulation, is poorly tolerated and compensated. If the arterial blood flow continues, the acute interruption of the venous blood flow leads to vascular congestion in the head with consecutive cyanosis, soft-tissue swelling, and petechial hemorrhages (Figure 1).

Petechiae are punctiform extravasations of blood; they are a classic symptom of venous congestion and occur preferably in the conjunctivae of the eyes, the oral mucosa, and the skin behind the ears, although they can generally be found anywhere above the level of compression. At autopsy, they can also be detected on inner surfaces such as the root of the tongue and the epiglottis, the perimysium of the temporal muscles, and the periosteum of the skullcap. Massive congestion can even be associated with bleeding from the mouth, nose, or ears.

Autopsy Findings

The mechanism actually responsible for death, namely, hypoxia, cannot be detected at autopsy, because after death the oxygen is used up in all body tissues. However, the pressure force itself may cause local damage: Bruising of subcutaneous and muscle tissue as well as fractures of the laryngeal cartilages and the hyoid bone occur as direct consequences of pressure and tension forces. Cyanosis, petechiae, and sometimes also blood extravasations from the mouth, nose, or ears are morphological correlates of blood congestion in the head region.

Figure 1 Petechial hemorrhages in the conjunctiva of the left upper eyelid.

Apart from the local injuries on the neck and possible signs of congestion, further asphyxia-related, but unspecific, findings may be seen: blood congestion of the internal organs (whereas the spleen appears rather anemic), pulmonary edema (which is often hemorrhagic), overinflation of the lungs, a liquid state of the blood, and subpleural pulmonary hemorrhages ('Tardieu spots').

Reflex Mechanisms

The question whether reflex mechanisms play a part in strangulation-related death is controversially discussed. Just above the bifurcation of the common carotid artery, the so-called glomus caroticum is located, which monitors intravascular pressure by means of baroreceptors and controls blood pressure and heart rate via feedback systems. The impulses are sent to the brain and from there via the vagus nerve to the target organ, the heart. The vagus nerve belongs to the parasympathetic part of the autonomic nervous system and can cause a drop in the heart rate, a decrease of the cardiac output, and, in extreme cases, even a cardiac arrest.

The feedback systems are activated not only by an elevated intravascular pressure but also by external compression. According to the more recent literature, it seems questionable whether strangulation really causes reflexogenic cardiac arrest, especially in healthy victims. On the other hand, in the presence of preexisting vascular pathology, pressure exerted on the carotid sinus may actually trigger an excessive and potentially lethal reflex response.

Hanging

In many countries, hanging is the most common method of suicide. Homicide by hanging is very rare. Occasionally, suicidal hanging is simulated to cover up a previous homicide.

Accidents by hanging occur in both children and adults: in infants and toddlers, especially by becoming entangled in rods and strings, whereas older children may strangle themselves in playgrounds, for example, when a bicycle helmet gets caught in a jungle gym. Adult persons in nursing care (often suffering

from dementia) may accidentally strangle themselves with belt restraints. Most accidents, however, occur in connection with autoerotic practices.

Mechanism

Hanging involves compression of the cervical soft tissues by a noose running around the neck and fixed above it. Thus, the causative force results from the gravitational drag of the body's weight. In most cases, the compression force is sufficient to interrupt the blood supply to the brain with consecutive hypoxia. In addition, the air passages are often blocked.

The rapid loss of consciousness accompanied by muscular atony limits the chance of self-rescue. Survived attempts at hanging are rare; they are observed if the ligature breaks or some other person rescues the victim at an early stage.

Shortly after becoming unconscious, most victims develop spasms which may cause injuries mainly on the extremities. In the agonal phase, saliva may flow from the mouth in a vertical trickle pattern. Sometimes, sperm or stool is discharged. The heartbeat can survive the irreversible brain damage by several minutes.

Methods of Hanging

Not only cords and ropes but also belts, cables, straps, wires, clothes, strips of bed sheets, and shoelaces are objects frequently used as ligatures. For correctly interpreting a case, it is indispensable to know the type and appearance of the noose and the hanging device.

The noose need not encircle the neck completely; isolated pressure on the front of the neck is sufficient for effective strangulation. Apart from nooses with slipknots, open nooses are used. The knot can be movable or not, close to the neck or away from it. The point of suspension is not always located on the back of the neck, but also on its front or side.

For death by hanging, it is not necessary that the body be completely suspended. The gravitational pull of a partly supported body usually also effects a neck compression sufficient to cause death.

Hanging Mark

The skin of the neck usually shows a hanging mark or furrow reflecting the course of the noose and the respective device (**Figure 2(a)–2(d)**). Sometimes the hanging mark can be very discreet or even absent altogether, if the ligature used was wide and soft, the force exerted by the noose was small (in partly supported bodies), or if the body was suspended for a short time only.

In most cases, the noose runs upward ('ascending') toward the point of suspension. The furrow is usually deepest and most distinct opposite the knot and becomes more shallow toward the highest point of the noose. After removal of the hanging device, a superficial abrasion of the skin is often discernible, which tends to parch, resulting in a brownish discoloration with time. If the noose consists of several turns or if the hanging device has a relief-like surface, linear or patterned elevations ('ridges') with intracutaneous bleeding and/or fluid-filled blisters may be seen between the impressed

parts of the hanging mark. Sometimes soft textiles such as a scarf or a handkerchief are interposed between the noose and the neck as a cushion.

The appearance of the hanging mark depends on the nature of the ligature, the exerted tension, the duration of suspension, and the possible presence of any interposed material such as head hair, clothing, or jewelry. From a criminalistic point of view, it is essential to distinguish between suicidal, accidental,

and homicidal hanging, as well as postmortem suspension. It must be pointed out, however, that the local findings caused by the noose are not suitable to prove vital hanging.

Further External Findings

Depending on the position of the suspended body, hypostasis is localized in the deepest body regions, most often the lower

Figure 2 (Continued)

Figure 2 Suicidal hanging. (a) Plastic rope forming a single-turn noose with a fixed (unmovable) knot. (b) and (c) Right and left side of the neck showing a steeply ascending hanging mark. (d) Frontal aspect of the neck with a deep, parched furrow. (e) Anterior neck after removal of the skin and the sternocleidomastoid muscles: The cranial aspects of the collar bones show blood extravasation at the sites where the muscles had been attached. (f) Anterior aspects of the lumbar spine with Simon's hemorrhages at the level of the intervertebral disks.

extremities, hands, and forearms. The course of the noose and the drag acting on the ligature decide whether only the venous vessels of the neck are occluded or whether both veins and arteries are affected. The tip of the tongue is often wedged between the front teeth and parched brown.

Blood congestion in the head may be completely absent (in the majority of cases), but may also be very pronounced. If the body is freely suspended and the knot is located on the back of the neck or in the occipital region, the decisive pathomechanism will be the interrupted blood perfusion of the brain; then, no congestion of the head is observed, as the blood flow through the arteries is stopped by the tightening noose. In highly atypical hanging situations (e.g., with the body sitting, kneeling, or lying) and/or when the point of suspension is on the side or front of the neck, sometimes only the thin-walled veins, but not the arteries of the neck, are occluded so that blood congestion can develop above the level of strangulation.

Autopsy Findings

The hanging mark is typically not bruised, as the pressure of the noose prevents blood from leaking from the affected vessels. On the other hand, blood extravasations are often seen at the origin of the straight neck muscles (**Figure 2(e)**). This is due to the strain exercised by the drag of the suspended body.

Pressure exerted on the anterior neck region displaces the hyoid bone and the larynx against the bony support of the spine. As long as these structures are still deformable, as in young persons, injury need not necessarily occur. With advanced ossification (in older and especially in male individuals),

the probability increases that hanging will cause fracture of the superior horns of the thyroid cartilage and/or the greater horns of the hyoid bone. The laminae of the thyroid cartilage and the cricoid cartilage are rarely affected. Although fractures of the larynx and the hyoid bone are indicative of a deformation due to pressure, they are not life threatening per se.

In rare cases, victims of hanging show transverse intimal tears in the common carotid arteries due to overstretching. In survivors, such intimal tears may cause secondary complications, for example, thrombosis or dissection of the vascular wall. A common finding – especially if the body was (almost) completely suspended – is found along the lower thoracic and lumbar spine, namely, streaky blood extravasations on the frontal aspects of the intervertebral disks ('Simon's hemorrhages', **Figure 2(f)**).

Bony lesions of the upper spine are rare and were most frequently described in the context of 'judicial hangings.' Fracture dislocation with transection of the cord will occur only if the body falls from a sufficient height before the noose around the neck tightens. Dislocation is typically seen between the second and third cervical vertebra. If the length of drop is several meters, complete decapitation may occur (**Figure 3(a)** and **3(b)**).

Strangulation by Ligature

Strangulation by ligature is most often encountered as a homicidal or suicidal act. In homicides, it is not uncommon that ligature strangulation is combined with other forms of violence. In suicides by ligature strangulation, knots and/or ligatures with multiple turns prevent subsequent loosening of the noose.

Figure 3 Decapitation from suicidal hanging (rope fixed to balcony railing). (a) Hanging device (plastic rope). (b) Head severed from the body at the level of the hanging mark.

Fatal accidents are rare, the more so as moderate compression of the neck does not lead to immediate unconsciousness. Under unfortunate circumstances, clothes worn around the neck such as a scarf or a tie may get caught in machinery. Accidental self-strangulation is also seen in autoerotic practices. Survived ligature strangulations occur in attempted homicides, rape, and other criminal offences.

Figure 4 (Continued)

Mechanism

In homicidal ligature strangulation, compression of the cervical soft tissues is mostly effected such that the assailant pulls apart the crossed ends of the noose with his hands. Powerful tightening of a collar or scarf may have the same effect. Contrary to the hanging noose, the constricting object is typically not fixed to a structure away from the body. The circular pressure exercised on the cervical soft tissues mostly leads to a combination of asphyxia, venous blood congestion, and more or less pronounced obstruction of arterial blood supply. This combination is characterized by congestion of the head with soft-tissue swelling, cyanosis, petechial hemorrhages, and sometimes bleeding from the mouth, nose, or ears.

Ligature Mark

The typical strangulation mark encircles the neck almost horizontally and is usually not as deep as the furrow seen in hangings (Figure 4(a)–4(c)). When there was a dynamic fight between the assailant and the victim, even a ligature with only one circular turn may produce a highly variable ligature mark imitating multiple loops and showing an ascending or descending course. The individual findings depend on the nature of the ligature (width, roughness, and surface pattern) and the strength of the assailant in relation to the victim.

Figure 4 Suicidal strangulation with a cushioned ligature. (a) Original findings at the scene. Note the cyanotic discoloration of the facial skin in comparison with the pale skin below the level of strangulation and the protruding tongue. (b) Strangling device after removal from the neck. (c) Parched ligature mark horizontally encircling the neck.

The ligature mark may present only as a circular streak without hypostasis (**Figure 5(a)–5(c)**). After at least partial abrasion, the unprotected corium tends to parch and assumes a brownish leathery appearance. The presence of congestion signs above the strangulation level suggests a vital traumatization (**Figure 6(a)** and **6(b)**).

Autopsy Findings

Concomitant findings are blood extravasations in the subcutaneous fatty tissue and the cervical muscles, fractures of the larynx and/or the hyoid bone, as well as signs of congestion at the root of the tongue. The hemorrhages may be caused either directly by the pressure of the ligature or indirectly by blood congestion.

Figure 5 Suicidal self-strangulation with a scarf. (a) Ligature fastened with a simple knot on the front of the neck. (b) Close-up view of the ligature on the left side of the neck. (c) Findings after removal of the ligature with shallow impression of the skin, but without any parching.

Figure 6 Homicidal ligature strangulation. (a) Congestion and cyanosis of the face with bleeding from the nose. (b) Close-up view of the horizontal ligature mark with partial discoloration from parching.

Whether laryngeal/hyoid fractures occur is not only dependent on the intensity of the cervical compression, but also on the degree of ossification of the primarily cartilaginous structures.

Manual Strangulation

Virtually, all manual strangulations with fatal outcomes are homicides. Recently, accidental deaths have also been observed in young persons trying to get a 'kick' out of the hypoxia resulting from manual compression of the neck.

Mechanism

Manual strangulation involves compression of the neck by using either one or both hands or by exercising pressure with

Figure 7 Homicide by manual strangulation. Multiple grip marks (excoriations and/or hematomas) on the front of the neck and at the level of the lower jaw.

another part of the body such as the forearm or knee. This can trigger different pathomechanisms: Prolonged compression of the larynx impairs the exchange of gases and causes asphyxia. Compression of the lateral parts of the neck may occlude the great cervical vessels. Dependent on whether strangulation is carried out with one or both hands, the assailant is rarely able to completely interrupt the arterial blood flow to the head. If the venous blood flow is mainly obstructed and the arterial blood supply continues at least to some extent, a congestion syndrome will develop. Consequently, asphyxia and venous congestion are the main pathophysiological mechanisms. As in strangulation by ligature, the typical findings are congestion of the head with (at least temporary) cyanosis, petechial hemorrhages, and sometimes bleeding from the mouth, nose, or ears.

Skin Marks from Manual Strangulation

Local skin lesions from the throttling grip of the assailant are the most important external finding (Figure 7). Intra- and subcutaneous hematomas, skin abrasions, and erythematous markings may be present on the anterior and lateral neck, in the mandibular region, and the nape. Typical findings are round, oval, or confluent bruises caused by the pressure of the fingertips as well as scratch-like and crescent-shaped abrasions from the fingernails. External findings on the neck may be insignificant or even completely absent, if the pressure was exercised over a large area or a soft object such as a cushion or scarf were interposed.

Autopsy Findings

By dissecting the cervical soft tissues layer by layer, blood extravasations can be identified in the subcutaneous fatty tissue, under the perimysium of the muscles and below the fibrous capsule of the thyroid gland as a consequence of direct pressure. Fractures of the hyoid bone, the thyroid cartilage, and the cricoid cartilage with concomitant hematomas in the surrounding connective tissue are common, but by no means

obligatory. Especially in children and young women, the laryngeal structures are cartilaginous and highly deformable, so that fractures do not necessarily occur.

In the marginal and apical portions of the tongue, one often finds hemorrhages caused by squeezing of the tissue between the teeth of the upper and lower jaws. In addition, subepithelial congestion hemorrhages may be discernible at the root of the tongue. A high percentage of victims show not only local findings on the neck, but also concomitant injuries on other parts of the body. These are mostly due to blunt traumatization, for example, hematomas caused by blows to the face or defense injuries on the upper extremities. By defending themselves, the victims often cause injuries on the assailant's body (scratch-like excoriations from fingernails, bite marks, etc.).

Victims surviving acts of manual strangulation may show mere reddening of the cervical skin as a sign of mechanical irritation or 'classical' grip marks such as hematomas and abrasions. Petechial hemorrhages in the conjunctivae tend to merge and then resemble an extensive hyposphagma.

Petechial hemorrhages in the facial skin and conjunctivae are actually one of the typical consequences of strangulation, both manual and by ligature, but they are not specific, as they may also have other causes (expulsive labor, fits of coughing, etc.).

Clinical symptoms after survived strangulation include dysphagia, local tenderness to pressure, pain on moving the neck, and dysphonia (hoarseness). Swelling and space-occupying hemorrhages in the cervical soft tissues may cause delayed life-threatening respiratory obstruction. Prolonged strangulation is often associated with loss of consciousness and involuntary discharge of urine and/or feces.

Traumatic and Postural Asphyxia, Physical Restraint

PH Schmidt and M Kettner, Saarland University Medical School, Homburg/Saar, Germany

© 2013 Elsevier Ltd. All rights reserved.

During physiological breathing, inspiratory and expiratory movements assure a constant exchange of ambient and intrapulmonary air, thus satisfying the organism's oxygen requirements. Breathing movements depend on the coordinated action of the respiratory muscles, which are under the control of the brainstem respiratory center. Breathing in a neutral body position without physical stress is mainly dependent on contractions of the diaphragm (abdominal or negative-pressure breathing) and/or contractions of the external intercostal muscles (costal breathing). These contractions generate negative intrathoracic pressure, allowing the lungs to expand. Expiration is accomplished by relaxation of the inspiratory muscles and elastic recoil of the lungs.

During deep inspiration and expiration, the involvement and coordination of respiratory muscles are more complex. The external intercostals, scalenes, minor and major pectoralis, sternocleidomastoid, and serratus anterior muscles pull the ribs up and out, and the diaphragm contracts, thereby pushing the contents of the abdomen toward the pelvis. During forced expiration, the internal intercostal muscles pull the ribs down and in, and the abdominal muscles contract, pushing the abdominal contents toward the diaphragm. Recruitment of the involved muscles is always dependent on their capability to contract, which, among other things, is determined by body posture.

Deaths attributed to traumatic asphyxia, positional or postural asphyxia, and physical restraint share a common mechanism, which is the mechanically induced inability to recruit respiratory muscles (and thus allow chest cage excursions) that is caused by either mechanical compression of the chest or a particular position of the body. These deaths can thus be subsumed under the term mechanical asphyxia. To differentiate between these subdiagnoses, the exact circumstances of death must be included in all forensic considerations. However, the unequivocal determination of the cause of death as traumatic asphyxia, positional/postural asphyxia, or physical restraint may not always be possible because of the fluid transition between these entities, for example, death associated with wedging. In some cases, the chain of events includes elements of more than one subdiagnosis, and, in other cases, a specific mechanism cannot be categorized as traumatic-, positional-, or restraint-associated. Furthermore, clear classification of a specific case may be impossible because of a combination of additional cofactors leading to death. Therefore, it has to be stressed that the diagnosis of these entities is mainly a diagnosis of exclusion, with the constant need to improve the diagnostic tools being used.

Traumatic Asphyxia

Traumatic asphyxia was first described by Ollivier d'Angers in 1837, when he noticed the relatively uniform morphological

features of decedents who had been trampled by crowds on the Field of Mars in Paris on Bastille Day of the same year. Over 60 years later, the morphological signs seen by d'Angers were integrated into Perthes' concept of pressure congestion, which provided the first explanation for the distinct discoloration and pattern of petechial bleeding (Table 1). It showed that the absence of venous valves in the inflow region of the superior vena cava allowed for the reflux of venous blood associated with chest compression into the neck and head region.

In cases of traumatic asphyxia, the restriction of respiratory movements and chest wall excursions is caused by external compression of the chest or upper abdominal region, for example, by a heavy object, matter burying the victim (landslide), or by being trampled by a crowd of people. From a pathophysiological perspective, massive compression of the chest or upper abdomen inhibits the inspiratory movements that provide not only oxygen to the organism but also the negative intrathoracic pressure needed to transport blood to the right heart. In addition, it causes reflow of blood to the neck and head region, which leads to cessation of cerebral blood flow, thus resulting in loss of consciousness and, ultimately, death.

Traumatic asphyxia may occur in accidental as well as homicidal settings. Accidental traumatic asphyxia is a frequent occurrence in severe automobile accidents, when occupants have been wedged between parts of the vehicle. It also appears as riot crushes in mass disasters, such as during the 2006 Hajj in Saudi Arabia, and the soccer game riots in Bradford (UK) and Brussels (Belgium) in 1985 and in Hillsborough (UK) in 1989. It occurs during construction accidents, for example, when workers are wedged between a wall and sliding soil or are trapped under heavy machinery. Children are especially at risk of being trapped under heavy objects, such as unbolted cupboards. In all these cases, the considerable weight disparity between the compressing object or force and the compressed person has been reported to be an important predictor of outcome, along with the duration of compression.

Crushing a person with a heavy object has also been described as a means of homicide. Other homicidal settings for traumatic asphyxia include compression of a victim's chest by the aggressor's use of thighs and knees ('leg scissors'), possibly leading to 'jack-knife' injuries or in the case of a child 'accor-dion' compression of the thorax.

Typical but rather nonspecific external findings in cases of traumatic asphyxia include significant purplish-red discoloration, edema, mucocutaneous bleeding, including petechiae and subconjunctival ecchymoses of the head and neck, and ecchymoses on upper body parts, which occur depending on the degree of compression and the body level where compression is applied, and that spare pressure points. In some cases, petechial bleeding may also be seen in the lower limbs, such as in the popliteal fossa. In cases surviving traumatic asphyxia, the discolorations resolve without a xanthochromic stage, whereas

Table 1 External findings in traumatic asphyxia

External findings in cases of traumatic asphyxia (Perthes pressure congestion, Ollivier syndrome)

- *Masque ecchymotique*: discoloration of the face, neck, and upper parts of the body (depending on the location and degree of congestion)
- Discoloration absent at pressure points (clothing trapped between object and skin, object contact areas)
- Facial and neck edema
- Mucocutaneous petechiae, subconjunctival ecchymoses
- In cases surviving traumatic asphyxia: nonxanthochromic disappearance of face and neck discoloration

Table 2 Internal and microscopic findings in traumatic asphyxia

Internal and microscopic findings in cases of traumatic asphyxia

- Internal petechiae and ecchymoses (e.g., pharyngeal, nasal, laryngeal, epiglottic, tracheal, subpleural, and subepicardial)
- Pulmonary congestion with subsequent edema
- Cerebral edema and petechiae
- Fractures, (e.g., ribs, clavicles, and sternum)
- Lacerations of abdominal organs (e.g., spleen)
- Retinal hemorrhages (Purtscher syndrome)
- Tympanic hemorrhages
- Pulmonary microembolism (fat and bone marrow)
- Hypoxic changes in internal organs (e.g., vacuolization and swelling of hepatocytes)

concomitant ecchymoses from other causes show xanthochromia before resolving. Neurological and other sequelae may include loss of consciousness, obnubilation, convulsions, agitation, disorientation, atonic motor paresis, transient hearing loss caused by tympanic hemorrhage, and vision disorders caused by retinal hemorrhage and edema (Purtscher retinopathy).

In addition to the external findings, autopsy may reveal internal petechiae and ecchymoses, and congested internal organs, including pulmonary and cerebral congestion. Moreover, lacerations of internal organs such as the spleen and liver, and fractures may be seen. Microscopic examination has found hypoxic changes attributable to asphyxia in various organs including vacuolization and swelling of hepatocytes, renal tubular epithelial cells, and cardiomyocytes. In addition, bone marrow and fat microemboli from bone fractures may be seen in the lung (Table 2).

Traumatic asphyxia may be established as the cause of death in the presence of the typical findings as described, and in the absence of other fatal injuries or competing natural causes of death. Toxicological analysis of autopsy specimens must be performed to exclude intoxication or incapacitation caused by alcohol or drug intake.

Postural or Positional Asphyxia

Postural or positional asphyxia have been defined as a fatal condition resulting from unusual orientation of the body,

Table 3 Diagnostic criteria for positional asphyxia in cases of accidental asphyxial death

Diagnostic criteria for positional asphyxia

- Discovery in a position precluding normal breathing, or interfering with pulmonary ventilation
- Evidence that the decedent placed himself/herself in the position inadvertently, that is, without deliberate action of another person
- Reasonable explanation that the decedent could not extricate himself/herself from the fatal position
- Exclusion of other unnatural causes of death (e.g., intoxication) with a reasonable degree of certainty
- Cardiovascular or respiratory or other potentially life-threatening disease: if present, unrelated to the terminal episode or, alternatively, feasible as predisposing to positional asphyxia

either induced or voluntary, that mechanically interferes with pulmonary ventilation by obstruction of the airways and interference with chest wall excursions. It is further characterized by the inability of the individual to extricate him or herself from the position, which may have a variety of causes, including intoxication (alcohol and drugs), neurological impairment, physical impairment, physical restraint, loss of consciousness, or a combination.

In positional asphyxia, death is attributed to impairment of ventilatory function caused by a body position that results in either compression or occlusion of the airways at different levels or the inability to perform inspiratory and expiratory movements. Pathophysiologically, the underlying mechanism can be determined from the circumstances surrounding death. The diagnosis of death due to postural/positional asphyxia therefore strongly depends on information regarding the exact position of the body upon discovery of the decedent and the autoptical and toxicological exclusion of other natural or unnatural causes of death (Table 3).

Positional asphyxia has been reported as the cause of death in a wide spectrum of death scenarios and subsequent autoptical findings. Cases of hyperextension of the trunk and neck region, for example, falls down stairs that result in a head hyperextension against an adjacent wall (Figures 1 and 2), or the body in a knee-chest position with rotated head and hyperextended neck, have been categorized as positional asphyxia. Cases of hyperflexion of the neck and the abdominal region, for example, recreational suspension or being trapped in bathtubs or tire piles ('jack-knife position'), have also been categorized as positional asphyxia. Whereas death may be attributed to compression or occlusion of the airways in cases of hyperextension of the neck with or without a rotatory component, in neck and abdominal hyperflexion, incapacitation of respiratory muscles is the major pathophysiologically mechanism. Both scenarios have been well documented in many cases, which frequently show an additional aggravation by the consumption of alcohol found in a large number of positional asphyxia decedents.

Alcohol has been shown to decrease total peripheral vascular resistance, arterial blood pressure, heart rate, and myocardial contractility. Furthermore, the occurrence of supraventricular and ventricular tachyarrhythmias and an increased endogenous catecholamine response have been observed. In addition,

Figure 1 Positional asphyxia: side view (a) and top view (b) of a 23-year-old individual in a prone position, who fell down the staircase under the influence of alcohol (blood alcohol concentration 2.60 g l^{-1} ; urine alcohol concentration 3.26 g l^{-1}). Body position with maximum hyperextension of the cervical and lumbar spine. Position of upper and lower limbs does not indicate unsuccessful self-extrication attempts. Images courtesy of Dr. S. Padosch.

alcohol may exert a central depressant effect on the respiratory center in the brainstem, thus fatally aggravating the mechanical impairment of ventilation.

Cases of reverse suspension (head-down position) have been described associated not only with sports accidents in particular (alpinists, speleologists, and parachutists), but also

with accidents resulting from certain sexual activities. In all these cases, hydrostatic pressure increases in the upper body, which does not have compensatory mechanisms such as the venous valves of the lower body. Increased hydrostatic pressure results in the pooling of blood in parts of the upper body and diminished flow of venous blood to the right heart, with subsequent hypovolemic shock. In crucifixions, death may be attributed to a combination of dehydration, hypovolemic shock, and mechanical or positional asphyxia, since both chest cage and intercostals are fixed in an extreme inspiratory position during the process of raising up the crucified individual.

In addition to the pathophysiological considerations underlying the mechanical components of positional asphyxia, additional impairment must be considered. Not only pre-existing organic diseases, but also physical stress, panic-induced catecholamine release, and consequent arrhythmias of a heart already sensitized by an elevated level of exercise and hypoxia may contribute to the occurrence of death. According to the concept of death caused by exposure to abnormal stress ('critical stress'), death occurs if the capacity of the organism is exceeded. If the organism is already impaired by other independent factors, the primary stress level is elevated to a secondary stress level, and an additional lower level of stress will exceed the critical capacity causing the death of the individual. With reference to positional asphyxia, the level of primary stress may be markedly elevated by preexisting medical conditions, alcohol, or drugs, and positional asphyxia becomes the ultimate insult that exceeds the limit of critical capacity (Figure 3).

As with traumatic asphyxia, the relatively nonspecific external findings of positional asphyxia include petechial bleeding (skin and conjunctivae) in addition to cephalic congestion and swelling, which have been found in up to 50% of positional asphyxia cases. Subject to the position of the body upon discovery and the underlying mechanism leading to this position, external examination of the decedent may yield varying patterns of scratches, hematomas, and abrasions, and a distinct distribution pattern of postmortem hypostasis, which corresponds to the scene of discovery.

Findings on internal examination may include congestion of the base of the tongue, the epiglottis, and the trachea. Congestion and edema of the brain and the lungs (with the mean combined lung weight amounting to more than 1000 g) are observed. Hemorrhagic infiltration of chest and neck muscles indicates rupture of muscle fascia, which is caused by strained respiratory movements attempting to compensate for constriction imposed by body position. During the convulsive phase, hemorrhaging may occur, which may be located in the muscles of the axillae and upper back, and in the major pectoralis muscles, as well as in the periosteum of the clavicle at the junction with the sternocleidomastoid muscle. In cases associated with abdominal suspension, bruising of the chest wall and diaphragm, peripancreatic hemorrhage, and rupture of the spleen may be seen. In addition, there may be underlying organic diseases that are not inherently lethal, but may lead to collapse into a lethal position, from which the victim is incapable of extricating himself/herself because of weakness, paralysis, or loss of consciousness. In cases of suspected positional asphyxia, toxicological analysis of autopsy specimens is mandatory for determining the reasons for incapacitation of

Figure 3 Stress levels and critical capacity exceedance in positional asphyxia. Adapted from Schoenmackers J (1950) Grenzbelastung und überraschender Tod. *Medizinische Klinik* 45: 790–795; Padosch SA, Schmidt PH, Kröner LU, and Madea B (2005) Death due to positional asphyxia under severe alcoholisation: Pathophysiologic and forensic considerations. *Forensic Science International* 149: 67–73; Byard RW, Wick R, and Gilbert JD (2008) Conditions and circumstances predisposing to death from positional asphyxia in adults. *Journal of Forensic and Legal Medicine* 15: 415–419.

the decedent, and for excluding agents of intoxication, which may in themselves be responsible for the occurrence of death.

In summary, fatalities caused by positional asphyxia are characterized by the scarcity and nonspecificity of morphological findings. Positional asphyxia must be identified as the major factor in the cause of death, although other factors may have been involved and contributed to the occurrence of death at a certain time, but by themselves could not be responsible for death. Autopsy results serve either to confirm conclusions drawn from thorough assessment of the scene or to identify injuries or other evidence that implicates the involvement of another person or persons. Furthermore, the autopsy serves to diagnose probable risk factors and exclude other natural or unnatural causes of death.

Restraint Asphyxia

As the term ‘positional asphyxia’ implies passive or accidental entrapment of the decedent, the term ‘restraint asphyxia’ was proposed to identify the sudden deaths of individuals in a restrained prone position. This has included many cases that were hogtied (restraint of a person with wrists and ankles behind the back and bound together by means of a cord or hobbling device). When this method has been employed by law enforcement authorities to incapacitate a suspect, additional weight (normally, body weight) was usually placed on the chest of the suspect. In other cases of restraint asphyxia, acutely psychotic patients or other patients in mental health

clinics who were involved in altercations, died after being subdued by techniques such as the ‘therapeutic basket hold.’

Although the classical scenario leading to restraint asphyxia is well known to forensic experts, a comprehensive explanation for all deaths does not exist. However, many of the situations leading to death associated with restraint asphyxia share similarities. They are usually highly charged, with the individual behaving irrationally (in some cases, referred to as excited delirium, caused by psychiatric disease and/or substance abuse), which leads to severe physical exertion on the part of others, who restrain the individual in a hogtied prone position. Furthermore, these decedents are preponderantly male and overweight, with a mean age of 30 years.

Clinically, the restrained person becomes quiet and develops cardiac arrest after a period of vigorous struggle. Hyperthermia seems to be present in most cases. Initial evidence supporting the adverse effects of the prone restraint position on ventilation and circulation was provided by a study of healthy subjects who were placed in the hogtied position after attaining a maximum heart rate of 120 beats per minute on a stationary cross-country ski track. The subjects in the restraint position exhibited a prolonged recovery time for both heart rate and peripheral oxygen saturation. The results of this study were not thought to be valid, because the method for determining oxygen saturation was believed to be inaccurate (no direct measure of ventilatory function and findings inconsistent with results from exercise physiology). Therefore, in a successive study, healthy volunteers underwent pulmonary function testing (PFT) in a sitting, supine, prone, and body

restraint position. In a second series of experiments, they were exposed to a 4-min exercise period followed by a 15-min period either sitting or in the restraint position. Serial arterial blood gas measurement, electrocardiography, pulse oximetry monitoring, and PFT (forced vital capacity, mean forced expiratory volume, and maximal voluntary ventilation), found a progressive decrease in pulmonary function associated with body position (sitting to supine to prone to restraint), and exercise did not result in additional impairment. However, it is difficult to generalize the findings of these experiments to the relevant forensic conditions seen in restraint asphyxia, because of significant differences between the study and the usual cases of restraint asphyxia. The study volunteers were healthy, tested negative for alcohol and drugs, and had not experienced struggle or psychological stress.

In cases of restraint asphyxia, excited delirium was frequently induced by psychoactive stimulative drugs, especially cocaine. Cocaine causes extreme sympathetic activation by blocking the presynaptic uptake of catecholamines, dopamine, and serotonin, which leads to increased myocardial contractility, blood pressure, and heart rate. Coronary artery vasoconstriction, microvascular resistance, and enhanced thrombogenicity of blood also exacerbate the physical condition of the cocaine user. Sympathetic stimulation is further increased by verbal and physical interaction with the people attempting to control the individual manifesting delirium. Excited delirium is characterized by constant, purposeless, and often violent activity, coupled with incoherent or meaningless speech, hallucinations, and paranoid delusions and can predispose to sudden death by causing neurally mediated cardiac arrest. Recently, a hypothesis was proposed that some cases of unexpected death in custody might be attributed to a clinical syndrome called stress cardiomyopathy, and the findings have been compared to the findings in takotsubo cardiomyopathy.

In conclusion, the mechanism of death in restraint asphyxia may be a fatal cardiac dysrhythmia or respiratory arrest induced by an imbalance of increased cardiac oxygen demand and decreased oxygen delivery caused by the interaction of several factors. Psychiatric or drug-induced agitated delirium coupled with police confrontation generates catecholamine-mediated stress of the cardiovascular system. The hyperactivity associated with excited delirium, struggle with the police, and ventilatory work to overcome the restraint increase the demands for oxygen delivery. Finally, the hogtied position may inhibit movements of the chest wall and diaphragm, thus impairing ventilation in a situation of high oxygen demand.

External examination of cases of restraint asphyxia yields typical, nonspecific signs, including petechial bleeding (skin and conjunctivae) and a pattern of injury that may include hematoma, characteristic abrasions of the wrists and ankles, and lacerations caused by the previous struggle to restrain the decedent. Autoptically, preexisting medical conditions contributing to the occurrence of death may be found, but which are not sufficient to be monocausal causes of death. Furthermore, varying degrees of internal organ injuries caused by the applied physical force may be found. Toxicological analysis is a prerequisite in cases of suspected physical restraint and may explain the observed state of excited delirium, clarify the dosages and intake of prescribed drugs, or characterize an intoxication-related fatality.

Other Mechanical Asphyxia Cases

There are some cases in which either mechanical asphyxia is the sole cause of death but cannot be solely attributed to a traumatic event, certain body position, or application of restraint techniques, or mechanical asphyxia may not be the sole cause of death but may play a crucial role, for example, in a setting of homicide.

Mechanical Asphyxia during Institutional Restraint

Mechanical asphyxias during institutional restraint occur usually in bedridden or otherwise incapacitated patients of nursing homes and hospitals. A scenario, which is usually categorized as death due to positional asphyxia, is entrapment of a patient between bed rails and mattress. Subject to the body position, it may also be categorized as strangulation. In praxi, it is frequently not diagnosed, since medical staff may modify body position of the decedent during resuscitation efforts. In other cases, posey restraints, vests, or jackets used to restrain a patient in a highly charged situation may not have been used correctly. Fixation may be too loose, therefore allowing the body to slip through the posey restraint leading to a hanging position, which can be categorized as positional asphyxia or hanging subject to the body and head position. In addition, the restraint may not be fixed correctly to the bed. While the patient moves, he or she may slip off the mattress attaining a suspended position.

Incaprettamento

In 'incaprettamento,' a ritualized form of ligature strangulation associated with the Italian mafia, the decedent is usually found in a prone position with wrists and ankles tied together with additional ligature of the neck, which is connected to the lower extremities. This scenario is either arranged postmortem or used to let the victim strangle himself or herself, once the legs are lowered due to physical exhaustion. Scenarios similar to the above-mentioned may also be seen in autoerotic asphyxia deaths.

Burking

The term 'burking' originates from the type of serial murders committed in Edinburgh, Scotland, in 1827 and 1828 by William Burke and William Hare, who sold the cadavers of their victims to a local anatomist. 'Burking' refers to a method of killing that combines mechanical chest compression caused by sitting on the chest of the victim, with the simultaneous smothering of the victim by covering the nose and mouth and pushing up the lower jaw.

Constrictor Snakes

Deaths due to constrictor snakes, for example, pythonidae, are rare occurrences. In the few reports of authenticated fatal constrictor snake attacks, mechanical asphyxia due to chest compression was assumed as the cause of death. Upon discovery

the snake may display a characteristic silhouette and be unable to move or has died of asphyxiation during ingestion of the victim.

Immersion Deaths

B Ludes, Institut de Médecine Légale, Strasbourg, France

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The determination of the diagnosis of death by immersion is one of the most difficult tasks in forensic medicine. The death of a victim found in water is not necessarily related to drowning and the autopsy examination as well as complementary laboratory investigations must be performed to assess this diagnosis. These investigations comprise biochemical and histological analyses and the diatom test.

Immersion deaths can be considered as death by drowning defined as death due to submersion in a liquid. The fundamental mechanism of death in acute drowning is reversible cerebral anoxia and the consequence of drowning is hypoxemia.

Physiopathology

A series of phases have been described in the death by drowning, consisting of breath holding, involuntary inspiration, gasping for air, loss of consciousness, and death. The cerebral hypoxia leads to irreversible brain damage and death occurs. The irreversibility of the cerebral lesions depends on several factors such as the individual's age, previous health, breath-holding tolerance, and the temperature of the water. Consciousness is usually lost within 3 min of submersion. One of the questions is also to estimate the volume of water that has been inhaled. This volume ranges from a relatively small to a very large one. Large quantities of water can pass, after inhalation, through the alveolar–capillary interface and enter the circulation. A review of the literature showed that no evidence exists, that large volumes of inhaled water can increase blood volume, which can cause significant electrolyte imbalances or hemolysis or acute cardiac failure. The determining factor is the alteration of the pulmonary surfactant, which induces the collapse of the alveoli, leading to intrapulmonary shunting of blood via atelectatic pulmonary tissue and hypoxia due to a lack of pulmonary oxygen perfusion.

Another mechanism of hypoxia consists of a vagal reflex that may be induced by inhalation of water. This reflex increases peripheral airway resistance with pulmonary vasoconstriction, development of pulmonary hypertension, decreased lung compliance, and a reduction in ventilation–perfusion ratios. A kind of vasovagal stimulation by intense stimulation of cutaneous nerve endings or stimulation of nerve endings in the mucosa of the eardrum, pharynx, or larynx by sudden immersion of cold water can lead to a reflex cardiac arrest. The inhalation of a small quantity of cold water may also induce a laryngeal spasm, which could lead to lethal hypoxemia by airway closure, but this mechanism is not favored by Knight because of the long time during which the larynx must be kept closed and thus prevent entry of water. It is clear that neither autopsy findings nor biological tests give any evidence of drowning in those cases. Approximately 10% of the

drowned humans die during laryngospasm or breath holding without actually aspirating fluid.

The hydrostatic pressure of water on a person induces a significant increase in the work of breathing and the cardiovascular response is an increase in heart rate and cardiac output, which can induce cardiac arrhythmia particularly in a person with cardiovascular disease. Following prolonged immersion in cold water, hypothermia will be observed when the deep body temperature drops below 35 °C. Death by ventricular fibrillation and finally by asystole may occur due to very low body temperature.

Autopsy Findings

The autopsy must identify all pathologic lesions as well as evidence of drowning. The major sign of immersion is skin maceration, which begins within minutes in warm water and becomes visible after a longer time interval in cold water immersion. The skin becomes wrinkled, pale, and sodden like a 'washerwoman's skin.' First, these changes can be seen at the fingertips, palms, and the back of the hands, and, later, the soles. After a period, the thick keratin of the hands and feet becomes detached and peels off in a 'glove and stocking' fashion – the nails and hair become loosened after a few days – but no changes may be observed if the body is in the water for only a few hours.

Other immersion signs such as *cutis anserina*, postmortem distribution of hypostasis, and the presence of mud, silt, or sand on or in the body have been described but have no diagnostic value even if the external material (sand, mud, etc.) is found situated deep in the respiratory passage and in the stomach. In fact, if the body has been rolled by waves, the presence of this material is not an evidence of aspiration.

The signs of drowning depend on the delay of body recovery from the water and on the development of putrefaction phenomena, which alter the positive signs of drowning. In freshly drowned bodies, large amounts of froth can be present around the nostrils and mouth as well as in the upper and lower airways. This fluid is not a specific sign of drowning because it is similar in appearance to the edema of left ventricular failure, but, in cases of drowning, the volume of froth is generally greater than in the other cases.

Lung weights are usually higher in drowning cases but a normal weight is possible in some drowning cases and in 'dry-drowning' deaths caused by vasovagal reflex. In drowning cases, the lungs may be overinflated, filling the thoracic cavity, with the indentations of the ribs at their lateral parts, and being generally waterlogged, referred to as *emphysema aquosum*, but the absence of these signs does not exclude true drowning. The surfaces of the lungs are pale and crepitant. The fluid is trapped in the lower airways and blocks the passive collapse of the bronchi that normally occurs after death and the lungs do

not collapse. Subpleural blebs of emphysema may also be observed at the surface of the lungs. It is important to emphasize that no pathognomonic findings have been detected in other organs during autopsy, in cases related to drowning.

Postmortem injuries to the face, the back of the hands, knees, and toes from dragging along the bottom may be present. Evidence of animal activities may also be found on bodies that have spent a long time in the water. Accidental or suicidal injuries inflicted on a person before his or her falling or entering into the water can also be seen. Differentiation between ante- and postmortem injuries is a very difficult task because of the lack of the usual criteria of antemortem infliction, namely in perimortally sustained injuries.

Histology

The histologic analyses of the diagnosis of death by drowning must focus on the state of alveolar expansion, identification or exclusion of previous disorders, and detection of signs linked with hypoxia.

These investigations must be performed on all the organs and not only on the lungs in order to make the difference between a death by drowning and other causes of death in water.

There are no specific findings in drowning cases but some aspects linked with water aspiration will be highlighted. It must be taken in to account that putrefaction will often complicate the histologic examination. The changes in the lungs induced by the water aspiration are heterogeneous distributed and multiple sections must be examined to assess the diagnostic. Several staining techniques must be used such as hematoxylin and eosin (H and E), and stains for elastic fibers (orcein) and reticulin fibers (Gordon-Sweet). The most important histologic findings in the lungs are interstitial congestion, edema, alveolar macrophages, alveolar hemorrhage, and alveolar wall disruption called *emphysema aquosum*. *Emphysema aquosum* is morphologically characterized by empty and dilated alveoli explained by a wash-out effect of the water which may remove the macrophages from the alveoli. Another important histologic feature is the acute dilatation of the alveoli with extension, elongation, and thinning of the septa leading to a compression of the alveolar capillaries. In other closed organs, (brain, heart, liver) the histologic changes are not specific and are only indicative of hypoxia and are evident in acute congestion, localized perivascular extravasation and swelling of the capillary endothelia. The examination of the heart to eliminate a disease being involved in the death is of particular interest.

The Biochemical Markers

Most of the current biological and thanatochemical markers of drowning are actually not accepted by the forensic community because they do not provide any reliable evidence of drowning.

The bases of these tests are the physical and biochemical modifications that occur in the arterial blood compared to the venous blood; in freshwater drowning, such modifications may be due to the marked hemodilution by inhalation of large volumes of water, which pass through the alveolar-capillary interface and enter the circulation, and in saltwater

drowning, they may be due to the hemoconcentration caused by electrolyte shifts. It is important to remember that the cardiac hemodilution methods are limited by the lack of specificity and the lack of sensitivity caused by putrefaction.

The literature has reported on chemical changes in plasma not providing reliable evidence of drowning. It has been assumed that electrolyte shifts may be observed with blood volume changes such as hemoconcentration in saltwater drowning or hemodilution in freshwater.

Today, it is no longer accepted that differences in sodium, chloride, and potassium concentrations between the blood within the right and the left ventricles could be considered as a sign of drowning. In fact, such electrolyte concentration changes have been described in many other causes of death.

Strontium levels in blood have been particularly studied and have a diagnostic value in drowning in seawater. The strontium concentration must be higher in the drowning water than in living individuals.

In cases of seawater drowning, serum level of strontium is confirmed as the best parameter for diagnosis. In cases of freshwater drowning, this marker depends on the concentration of strontium in the water, which must be higher than the concentration in the serum of the victims. Several authors have proposed the detection of genes encoding small-subunit ribosomal RNA (16s rDNA) for plankton detection in tissues, allowing the diagnosis of drowning by this method. In fact, the qualitative or quantitative identification of various planktons could be employed for the determination of drowning. As most of the 16s rDNA sequences are relatively conserved, they contain a few variable regions. Sequence comparison of the variable regions of 16s rDNA can provide sufficient information to allow the discrimination of both, close and distant phylogenetic relationships. The interest of this method is the independence on the morphologic characteristics.

Two pairs of specific primers were designed according to the sequence information of a picoplankton in Lake Biwa, Japan, and used to amplify the segments of 16s rDNA. Other authors designed a set of phylum-special primers for selective amplification of the 16s rDNA segment of cyanobacteria and diatoms from a variety of natural settings and were able to identify different strains using denaturing gradient gel electrophoresis methods.

Detection of chlorophyll-related genes of *Euglena gracilis* and *Skeletonema costatum* was also proposed by several authors to identify plankton by molecular biology methods, but all these technologies give only qualitative results in demonstrating the presence of these algae in victim's tissues. The quantitative approach, provided by the concentration of diatoms in the tissues, that can be achieved by the diatom test is not possible by methods using molecular biology, which are not able to evaluate the site of drowning.

The Diatom Test

Diatoms belong to the bacillariophyceae, which are a class of microscopic unicellular algae involving more than 15000 species living either in freshwater or in seawater or brackish water. The cell structure of these algae is unique and consists of a frustule that is made up of two valves filling together to

enclose the cytoplasmic contents. This frustule is made of a hard siliceous skeleton, highly complex in shape, and extremely resistant to putrefaction, enzymatic or acid digestion, and to fire destruction. The classification of diatoms is based on the structure of their siliceous valves showing different symmetry, dividing diatoms into two main groups – centric diatoms and elongated or pennate diatoms.

The use of this test to assess the diagnosis of drowning is very controversial because such algae have been found at autopsy in nondrowned victims and there is the possibility of a false positive. Other authors have stated that under defined conditions, the diatom analysis is able to discriminate between drowning and nondrowning cases.

Following the figure of 20 diatoms per microscope slide set for lung findings allows for a sufficient concentration for the exclusion of sources of error. Our group proposed the following criteria for a positive test based on qualitative and quantitative diatom identification.

Analysis may be considered positive if 20 diatoms are identified per 100 μl of a pellet sediment extracted from a 2-g lung sample (Figures 1 and 2). For other closed organs (Figures 3–7), such as brain, liver, kidney, and bone marrow, more than five complete diatoms per 100 μl of a pellet sediment extracted from a 2-g tissue sample with the exclusion of fragments are required for confirmation of water inhalation. It is very

important to point out that in our experience, if diatoms were present in the organs, they were also present in the lungs, and when none were present in the lungs, none were found in other organs. About false-positive results, no diatoms were found in tissue samples from the control subjects.

Qualitative analysis allows for identification of the type of diatom and for comparison with those extracted from the

Figure 3 *Cyclotella stelligera* (diameter 20 μm), liver sample.

Figure 5 *Cocconeis placentula* ($24 \times 9 \mu\text{m}$), brain sample.

water samples (Figures 8–10) taken at the site where the victim was found. In our experience and also as considered by other authors, false-positive cases can be excluded by the comparison of quantitative analysis, identification, and comparison between species found in the water and those in the tissue samples.

The water samples are collected according to a strict protocol. Two samples of 100 ml of water, each containing diatoms

sampled by scraping stones found in adjacent water, are collected in clean containers at the site where the body was found or where the immersion is believed to have occurred. All reagents and glass containers must be assessed for the presence of contamination by diatoms, and diatom-free water used to prepare reagents. Contamination from exogenous diatoms can occur during autopsy itself by contact with algae attached to the clothes and skin of the victim. So, the method of sampling needs strict protocols to avoid contamination by diatoms at the steps of the analysis.

This test cannot be used reliably to establish the diagnosis of drowning when the immersion water contains few or no diatoms, which is the case in bathtub drowning or in winter when drowning occurs in iced water.

Due to the seasonal variations of the concentrations of diatoms, which are present all the year round in rivers and lakes, a water-monitoring program was set up to monitor the diatom populations in the main rivers in our area. This monitoring showed that the diatom profiles of each river appear to be specific if one considers the five most frequent species in a given month. In a given river, the same diatom profiles could be determined but the relative abundance of each diatom varies along the course of the river. A particular

Figure 10 *Stephanodiscus neostreae* (diameter $25 \mu\text{m}$), water sample.

algae profile can be linked to a pollution source and can be so far a marker of a particular site of drowning.

The qualitative analysis of the diatoms reflects the ecologic properties of the environment in which the death had taken place. The site of drowning may be determined by comparison of water samples with the lung samples. In fact, the lungs can show the diatom profile of the inhaled water, but, due to their size, the diatoms found in the other organs are less than 50–60 µm in diameter, leading to the possibility of their passing the alveoli–capillary barrier even after destruction of the alveoli by the water.

The possibility of indicating whether drowning occurred in freshwater, brackish water, or in the sea was also described.

The quantitative analysis criterion is crucial for the interpretation of the results, but more essential is the qualitative comparison between the diatom microflora in the immersion water and the diatoms found in the tissues.

With respect to these two criteria, the diatom test avoids false-positive results due to contamination of exogenous origin or from the laboratory.

Conclusion

The diagnosis of drowning is one of the most difficult tasks in forensic medicine; if it is a fresh body, some autopsy findings can give an indication of death by drowning, but they are not specific enough; these findings are absent in putrefied bodies. Therefore, lung microscopic observations and biological or diatom tests were developed. The microscopic studies may provide some reliable results in fresh lung samples, sometimes with a lack of specificity, and the biological tests are still controversial according to the literature. The determination of strontium levels in blood and in water samples is proposed in seawater drowning or in freshwater drowning; the diatom test may be the most reliable analysis to assess the diagnosis of drowning in both fresh and decomposed bodies. The diagnosis of drowning can be proposed only after considering the totality of the investigations: the external examinations and autopsy, histologic analyses, microscopic observations, biochemical analyses, diatom tests, and a special glance at the circumstances of the death and the procedure of body recovery.

Sharp Trauma

U Schmidt, Freiburg University Medical Center, Freiburg, Germany

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Epigastrium The part of the upper abdomen immediately over the stomach.

Fibrin Insoluble protein formed from fibrinogen during the clotting of blood; deposition of fibrin is

also a response of different tissues to inflammation or injury.

Zygomatic bone The bone that forms the prominent part of the cheek and the outer side of the eye socket.

Introduction

Sharp-force injuries are the second most common cause of injury following trauma by blunt force. They are caused by sharp-pointed or keen-edged instruments, resulting in incised wounds, that is, cuts or slashes, stab wounds, or chop wounds, depending on the implement used and the manner of infliction.

Upon examination of sharp-force injuries, the forensic expert will be asked to differentiate between suicidal, homicidal, and accidental origins. Diagnostic findings, which are essential to make this distinction, include the following:

- kind of injury sustained by the victim (incised, stab, or chop wound);
- pattern of injuries, that is, their number and anatomical localization;
- characteristics of the instrument or weapon used;
- sequelae (e.g., from lesions to vessels and inner organs) or cause of death; and
- findings at the scene such as blood traces or bloodstain patterns.

Additional questions often raised in court are related to the level of force that had to be applied by the perpetrator, the chronological sequence of injuries inflicted to the victim, and the victim's capability of acting after traumatization.

Epidemiology

Partly owing to a restricted access to firearms, sharp force is the most frequent method of homicide in many European countries. Here, it accounts for about one-third of all killings, mostly by stabbing with knives. In the United States, killing by sharp force is second to gunfire. 80–90% of the perpetrators are male and aged between 20 and 40 years, which roughly corresponds to the general data contained in criminal statistics on homicides independent of how they were committed.

As regards the number of victims of sharp-force homicides, both sexes are almost evenly affected. As an exception, several studies from Scandinavian countries stated a considerably lower share of female victims (30% on average). Regarding bodily harm, male victims as well as male perpetrators are overrepresented, which is also in line with the circumstances generally known for acts of violence. As in other kinds of assault, a high percentage of offenders as well as victims are under the influence of alcohol and/or drugs of abuse.

Most frequently, sharp-force fatalities occur at the victim's home. This is especially the case when male perpetrators kill female victims, since homicides by sharp force often result from domestic conflicts between life partners. On the other hand, knife attacks involving a male perpetrator and a male victim often take place in the public space, as they frequently arise from personal disputes between (intoxicated) opponents.

According to the literature, sharp force accounts for 10.0–15.4% of attempted, but only for 2.0–3.1% of completed, suicides. Fatal injuries result more often from stabs to the chest (precordial region and epigastrium) and stabs/cuts to the neck than from cutting the wrists. The latter is frequently found in attempted suicides.

Accidental sharp-force fatalities are very rare. They account for ~2% of all sharp-force fatalities and for 0.3% of accidental deaths, respectively. In these cases, death is usually caused by exsanguination.

Self-inflicted injuries by sharp force are frequent in patients suffering from personality disorders, especially borderline personality, the majority of them being female adolescents. Apart from individuals with mental disorders, self-inflicted wounds are also seen in fictitious assaults and alleged sexual offenses. The wound morphology and the arrangement of the mostly superficial skin lesions often allow for a diagnosis on the spot.

Diagnosis is more difficult in cases of self-mutilation aiming at insurance fraud. Typical examples are chop wounds to the nondominant hand and fingers resulting in amputation of one or two digits, most often the thumb with the index finger ranking second.

Wound Morphology and Biomechanics

Blunt- and sharp-force injuries show some fundamental morphological differences allowing diagnostic differentiation. Contrary to injuries caused by blunt force, sharp-force injuries have cleanly severed wound edges, usually without concomitant abrasions or contusions. Tissue bridges between the wound edges, which are due to the unequal tear resistance of different types of tissues, are also absent in sharp-trauma injuries.

Incised Wounds: Cuts and Slashes

Cut wounds occur when a sharp-edged instrument moves in a direction tangential to the body surface. A cut formally describes an incision of the skin and the underlying soft tissue,

whereas a slash implies cutting with a violent sweeping movement. Depending on its position in relation to the cleavage lines of the skin, the wound may gape more or less in a spindle-shaped way with the greatest depth in the middle decreasing toward the wound ends (Figure 1).

This is to be expected especially if the cut is localized on a curved part of the body surface, for example, in a longitudinal cut wound across the zygomatic bone or a transverse cut on the upper arm or calf. Both wound ends are pointed often forming a superficial 'tail' or shallow incision. If the cutting edge is moved in an acute angle to the body surface, one of the wound edges is oblique, while the opposite one shows undermining. Sometimes, even a flap-like ablation of soft tissue can result. If cuts are located above bony structures (e.g., the skull), concomitant cut-like transection of the periosteum is occasionally seen (Figure 2). The only conclusion to be drawn from a cut wound is generally that it was caused by a sharp-edged instrument. The wound morphology alone usually does not provide hints as to characteristic features of the causative weapon/implement.

Stab Wounds

A stab wound is caused by a pointed object thrust into the body. In stabs to the trunk, the abdominal and/or thoracic cavities may be affected.

Under certain circumstances, some features of the stabbing instrument are reflected by the wound morphology. For example, a stab wound from a single-edged blade may show one sharply pointed end – corresponding to the cutting edge of the

blade – and one rounded end on the side of the knife's back (Figure 3). As in incised wounds, the wound margins can be beveled or undermined when the blade enters the body at an oblique angle.

According to the dynamics of knife attacks, there is considerable relative movement between the assailant and the victim, and an irregular wound configuration is often found. When the knife has plunged into the body, turning of the victim or twisting of the blade before withdrawal causes L-, Y-, or V-shaped wounds (Figure 4).

Atypically shaped wounds can also result from stabs through skin folds or creases. 'Incised stab wounds' result from a combination of cutting and stabbing movements. The

Figure 1 Cut wound on the right thigh of a 56-year-old man who was killed by sharp force and gunfire: clean-cut wound margins without any concomitant abrasions or hematomas. The wound shows its greatest depth in the middle decreasing toward the wound ends.

Figure 2 Cut wound on the forehead of a 59-year-old man who was killed by sharp force. The tangential movement of the knife led to flap-like ablation of the scalp. Also, the frontal bone's periosteum was severed.

Figure 3 Two stab wounds to the chest in a man killed by stabbing. As both wounds were inflicted with a single-edged foldable pocketknife, each of them shows a pointed wound end on the right side, and a more rounded end on the left side. The differing lengths of the skin wounds result from a differing depth of penetration and are related to the variable width of the tapered blade.

Figure 4 Abdominal stab wound in a young man who was involved in a fight between drunken opponents. The L-shape indicates that the blade was twisted in the body before withdrawal.

Figure 5 Incised stab wound on the neck of a 40-year-old man who was killed with a Swiss Army knife. Dissection of the wound track showed complete transection of the right common carotid artery and partial transection of the right internal jugular vein.

wound may start as a cut, which terminates as a stab wound; on the other hand, some stab wounds turn into an incised wound as the knife is withdrawn at a shallow angle (Figure 5). Incised stab wounds are frequently found in victims of knife attacks.

Conclusions drawn from a stab wound on the properties of the stabbing instrument are subject to some uncertainties. Owing to the elasticity of the skin, the width of the blade can only be roughly estimated even in the case of an orthogonal penetration without any additional cutting. Stab wounds associated with a hematoma or an imprint abrasion ('hilt mark') indicate that the blade was vigorously pushed in up to its end. The construction parts of the knife contacting the body surface may then be reflected by a patterned hilt mark (Figure 6). In this case, the length of the blade can be roughly estimated from the depth of the wound track, provided its end is clearly defined.

A vigorous stab up to the hilt can indent the soft tissues so that the depth of the wound track may exceed the length of the causative knife blade.

Where stable bony structures such as the spine are hit by a stab, the stabbing instrument may bend and occasionally parts of it (e.g., the tip) may break off and lodge in the wound track or quite often within the injured bone. Such fitting pieces found during autopsy help to identify the causative implement. When a knife is drawn over a bone or cartilage tangentially, the wound may reflect a serrated blade. The same applies to tangential movements across the skin in a transverse

Figure 6 (a) Back of a young woman killed by multiple stab wounds (numbering does not refer to chronological sequence). The perpetrator tried to cover up the crime by arson, which led to superficial burns on the right side of the victim's body. The weapon involved was a single-edged butterfly knife. (b) Stab wound showing square skin abrasions on its ends. These 'hilt marks' resulted from the knife's handle contacting the body surface when the knife was vigorously plunged into the body. Both wound ends are rounded due to the penetration of the ungrinded part of the blade ('ricasso,' near the handle) into the body.

direction to the blade, which may produce parallel abrasions on the skin. Stab wounds perforating parenchymatous organs or muscles occasionally show parallel lines reflecting the teeth of a serrated blade.

Stabbing instruments do not necessarily have to be edged, and there is a variety of pointed implements that are used to inflict stab wounds, for example, ice picks, forks, pens, scissors, and screwdrivers. When originating from such an implement, wound margins are often abraded. Wounds may show characteristic features, such as the flat Z-shaped injuries resulting from a closed pair of scissors or the four-point-star-shaped wounds caused by a Phillips screwdriver.

Chop Wounds

Chop wounds are caused by rather heavy objects with a sharp edge (e.g., axes, hatchets, cutlasses, and chopper knives) and/or very long blades (e.g., swords, sabers, and machetes). These objects sometimes cause injuries showing both sharp- and blunt-force elements, for example, additional fractures of the skullcap in blows to the head. Usually, heavy cutting weapons cause smooth-edged soft-tissue transections, although the wound margins may be abraded or contused when the penetrating object is wedge shaped as, for example, an axe. Of diagnostic significance is a smooth-edged skin and soft-tissue lesion combined with a notch-like injury of the underlying bone; this constellation indicates a sharp-force injury and suggests that a heavy cutting weapon was used (Figure 7).

Figure 7 Young man killed by sharp force using a chopper knife. (a) Chop wound on the right mandible, which is also cleaved. (b) Several pieces of the chopper knife's thin-edged blade broke off during the attack and were recovered from several wounds upon autopsy.

Injuries from Glass

Whenever broken bottles or pieces of glass are used for cutting or stabbing, the wound margins can show concomitant skin abrasions, notches, or hematomas (**Figure 8**). In 1929, Canuto described shallow epidermal transections on the wound ends which result from the keen breaking edges of the glass shards – so-called ‘Canuto’s ends.’ Due to the three dimensionality of glass shards entering the body, two parallel epidermal transections can be found in many of these wounds (cf. **Figure 8(c)**). Another morphological feature is the displacement of body hair into the wound track that has also been attributed to the thickness of the glass shards’ fracture surface. If stab-like injuries occur, splinters of glass may be found within the wound track as well, which facilitates the correct diagnosis. Valuable hints can often be derived from the findings at the scene, for example, broken glasses or bottles.

If an intact drinking glass is thrown against an individual, the glass may splinter as it hits the head, and resulting glass fragments or splinters can be found on the victim’s clothing or hair. In addition, the glass fragments can cause superficial lesions of undraped skin in the head and neck regions. However, experiments show that these wounds hardly exceed a few millimeters in depth; deep, penetrating wounds of the neck are not to be expected. They can occur, however, when a drinking glass or bottle is broken before throwing it. This relates especially to vigorously thrown glass shards with spike-like protrusions. Systematic studies on the injuring potential of thrown (household) knives are still lacking.

Figure 8 (a) Several injuries resulting from an accidental fall into a drinking glass, which splintered. The victim was a 64-year-old drunken woman. Fatal bleeding was conditioned by a preexisting coagulopathy due to liver cirrhosis. (b) The wounds show characteristics of a sharp-force injury, as well as concomitant abrasions, cuts, and hematomas (forehead). (c) Shallow epidermal cuts on the edges of an almost square wound end caused by a keen-edged glass shard (root of the nose/right eye).

The Physics and Dynamics of Stabbing

Numerous studies have been conducted to assess the thresholds of different physical parameters, which have to be passed to effect a stab wound on a victim's body. Many of these studies are based on specific questions related to the reconstruction of injuries, for example, whether it is possible to sustain a (fatal) stab wound by merely 'running or falling' into a knife. Already in the nineteenth century, reports were published in the literature stating that it cannot be entirely ruled out that at least stabs penetrating only the soft tissue are of accidental origin. For example, this may happen if the hand holding the knife is fixed in front of the trunk and no evasive movement is possible. The force or energy necessary for penetration not only depends on the stabbing impulse and velocity or the resistance of the different perforated structures (clothing, skin, soft tissue, internal organs, and bone), but also depends on the properties of the stabbing instrument used, especially the shape of the tip.

How far a stabbing object is able to penetrate essentially depends on the (elastic) resistance of the clothing and the skin, the presence of bony structures along the wound track, and also the reach of the arm holding the knife. Test stabs conducted by various authors showed that a mean force of 57–77 N was necessary to overcome the elastic resistance of uncovered skin. Additional layers of clothing increase these values by 62–112 N with tight-fitting clothes requiring a lower amount of force than loose-fitting clothes. Up to 200 N was necessary to perforate pigskin. The impact velocity measured ranged between 1–2 and 7 m s⁻¹ for stabs subjectively regarded as weak or vigorous by the test persons.

Additional aspects to be considered are the weight of the knife used, the geometry of the blade tip, and the angle of the blade's point (Figure 9): stabbing with a 'sheepsfoot' blade showing a straight cutting edge and curving back as in many bread knives will require higher penetrating forces than stabbing with a symmetrically pointed 'spear-point' blade or 'needle-point' blade. The latter one is highly tapered, often twin-edged, showing a long and narrow point. It is commonly referred to as a 'stiletto' or a 'dagger.' Household knives often show 'back-point' blades ('straight-spine' blades) with a flat

back and curved cutting edge or 'drop-point' blades with a convexly formed back. 'Clip-point' blades with a concavely formed back at the tip are often seen in Bowie, survival, and hunting knives as well as in pocket and other foldable knives. The smaller the angle of the blade's point, the lower are the forces required to induce a penetrating injury.

Depending on the structure of the bone, different amounts of force are necessary for perforation. Generally, one can assume that a submaximal stabbing impulse is sufficient to perforate thin bones such as the shoulder blade, the bones forming the eye sockets (especially the frontal and the zygomatic bone), and the temporal squama, as well as the ribs. Perforation of the temporal squama requires a force of about 250 N, parietal bone of about 500 N. However, in stabs effected with an elevated arm moving downwards ('overarm stabbing'), impact loading on the knife often approaches 1000 N; usual impact velocities range between 6 and 10 m s⁻¹.

An essential problem of the biomechanical investigation of stabbing processes is that there is still no validated model adequately simulating the mechanical properties of the skin of living human individuals.

Sequelae and Causes of Death

The predominant cause of death after sharp-force trauma is exsanguination. The pathological and anatomical diagnoses are made on the basis of sparse, inconspicuous hypostasis, pale internal organs with their characteristic color, a flaccid spleen with a wrinkled capsule, and the presence of striped subendocardial hemorrhages in the outflow channel of the left ventricle (the so-called exsanguinating hemorrhage).

Internal exsanguination is generally associated with a large accumulation of blood in the affected body cavities. The blood volume of an adult accounts for about 6–8% of his body weight. A loss of 1/3 of the blood volume is regarded as life threatening and of 2/3 as usually fatal. Other relevant factors are the speed of the blood loss, which depends on the type and the caliber of the severed vessel(s), and the localization of the injury. For example, if blood rapidly flows from a major arterial vessel into a preformed cavity, considerably smaller blood loss can already lead to death. In stab wounds of the abdominal region, the soft-tissue layers sometimes move in opposite directions after removal of the stabbing instrument so that no major external bleeding is seen. In spite of perforation of the abdominal wall and involvement of internal organs, the victim may retain the capability of acting until the clinical signs of blood volume deficiency become manifest, which may take several hours.

Cumulative surveys of the injuries found in criminal assaults and homicides with sharp-force trauma show that most injuries are localized on the chest and neck. This is attributed to the fact that a great number of offenses start with the victim and perpetrator initially facing each other in an upright position and that most stabs are effected with an elevated arm moving downwards. Consequently, lesions of the thoracic organs account for a large percentage of the potential sequelae and deaths. Stabs to the thorax may perforate the thoracic cavities and result in a pneumo- or hemothorax. A bilateral pneumothorax can be fatal because it restricts

Figure 9 Examples of common blade tip geometries. From left: Boning knife with straight back and curved cutting edge ('back-point' blade); butterfly knife with slightly curved back ('drop-point' blade); foldable knife with concavely curved back at the tip ('clip-point' blade); slightly tapered foldable knife with the point lying on the blade's longitudinal centerline ('spear-point' blade); bread knife with a curved back and a straight, serrated cutting edge ('sheepsfoot' blade).

respiration. If the lungs are affected and blood seeps into the respiratory tract, blood aspiration is an important proof of vitality, but massive aspiration of blood can also be fatal in itself.

Stabs to the heart can cause cardiac tamponade. If 150–200 ml blood accumulates in the pericardial sac, blood influx during the diastole is so severely impaired that cardiac arrest results from the compression of the heart. Smaller ventricular lesions may cause successively increasing tamponades with volumes up to several 100 ml. Even then, the victim may retain the ability to act for some time.

If large veins in the proximity of the heart, for example, on the neck, are affected, a negative pressure in these vessels can cause air embolism. Especially in stab and cut wounds of the cervical region, one always has to check at autopsy whether the right cardiac ventricle contains air. Gas volumes of 70–150 ml are considered sufficient for fatal air embolism.

Injuries involving the central nervous system may occur, though they are rare. They include stabs to the cerebral skull (temporal squama and orbita) with direct damage to the brain or intracranial bleeding.

Homicide, Suicide, and Accident

Fatal sharp-force injuries are mainly found in homicides. In the literature, the relation of homicides versus suicides ranges between 4:1 and 5:2. As stated above, accidents with a lethal outcome are very rare. Several cases of fatal bleeding due to incision of major vessels, for example, by architectural glass, have been reported, and – despite its rarity – a ‘break, enter, and die syndrome’ has been termed for such fatalities occurring during illegal break-ins. Thorough information about the situation at the scene is therefore indispensable to elucidate the course of an accident.

Various criteria have been tested for their significance and sensitivity as to diagnosing a homicide by sharp force and differentiating it from a suicidal act. Although the sensitivity of discriminating morphological criteria is not very high, some of them are satisfactorily specific. These are tentative or hesitation injuries in suicides and defense injuries in homicides. Tentative or hesitation injuries are mostly shallow cuts or minute stab wounds, which do not necessarily completely perforate the skin, and which can often be found adjacent to perforating injuries (Figure 10). Baring the injured area prior to cutting or stabbing suggests a suicidal act. It is important to realize that the reverse conclusion is not valid. As an example, less than half of the victims injured or killed by sharp force show defense injuries. So, the absence of defense injuries by no means excludes a homicidal act or an assault.

Relevant information can be derived from the pattern of injuries found on a victim's body. In suicides, injuries tend to be grouped in circumscribed body regions. They are preferably located in anatomical regions suggesting a fatal outcome. These include the precordial region; the epigastric angle where the apex beat – the cardiac impulse – can be felt; and regions where the pulse may be palpated, especially the wrists (radial artery) and neck (carotid artery), and also the cubital region (brachial artery), the hollow knee (popliteal artery), near the ankle joint (posterior tibial artery), and even the

Figure 10 ‘Tentative’ cuts and stabs in suicides. (a) Superficial cuts on the left side of a 53-year-old woman's neck, who used a scalpel to kill herself. Cause of death was exsanguination due to subtotal transection of the right internal jugular vein. (b) Multiple superficial stabs without any injury of great blood vessels in the left cubital region of a 39-year-old man.

temporal region (temporal artery – Figure 11). Injuries to the trunk are predominantly localized on the front of the body. The suicide's handedness and the accessibility or reachability of the injured areas also have to be taken into account: Thus, right-handers tend to inflict wrist cuts predominantly on their left arm. If the suicide retains the ability to act for some time, the victim may be able to clean or remove the object used.

Some additional criteria are considered to be predictive of either homicide or suicide: bone and/or cartilage wounds are more frequently seen in homicides than in suicides; the longitudinal axes of stab wounds to the chest tend to be horizontal in suicides resulting from the blade being inserted through an intercostal space; and multiple sharp-force damage to the clothing corresponding to the victim's injuries is more often seen in homicides, whereas the large majority of suicides bares the target region before cutting or stabbing. However, suicides stabbing the precordial region without baring their chests are no unusual finding; in these cases, associations with psychiatric disorders or acute intoxication with alcohol or drugs of abuse has been stated.

Another feature that is rarely mentioned is the observation of suicides showing extensive blood traces on their palms, which is usually not the case in victims of homicides unless they sustained defense injuries on their hands.

Last but not least, the findings at the scene and – if present – biological trace evidence have to be considered. Although there are some criteria helping to correctly diagnose a homicide, suicide, or accident, the decision has to be made for each individual case considering as much information as possible.

Figure 11 Suicide of an 86-year-old man by stabs to the chest. (a–c) Cuts in the left and right temporal regions. (d) Three stab wounds on the left side of the thorax with associated tentative injuries. Cause of death was a penetrating injury to the heart with pericardial tamponade and injury of the left lung with hemothorax.

Capability of Acting

For the reconstruction of an event, it is often necessary to assess whether the victim was still able to act after sustaining a stab or cut wound. In this respect, the capability of performing complex and targeted actions requiring full consciousness has to be distinguished from instinctive actions such as flight or defense reflexes. The decisive criterion of incapacitation is usually the onset of unconsciousness.

Immediate incapacitation after sustaining a stab or cut wound is relatively rare. This has been reported after injuries to the brainstem, for example, by a stab to the nape or through the posterior wall of the pharynx, after severance of both carotid arteries or after (almost complete) transection of the thoracic aorta with a sudden, significant fall in blood pressure. Lesions of the cerebrum or cerebellum by a penetrating pointed object need not necessarily lead to incapacitation. Essential factors for the rapid onset of unconsciousness are not only the size and anatomical localization of the affected brain area, but also whether major vessels are involved (especially the *arteria cerebri media* in stabs to the temporal region) associated with intracranial bleeding and possible blunt traumatization of the skull.

After stabs and cuts to the cervical region, it is by no means impossible that the capability of acting is retained for several minutes. This depends on whether the relatively well-protected major arteries and veins of the neck are affected at all, whether the vessel has been completely severed and whether the blood can freely escape from the injured vessel. After suicidal cuts to

the neck, considerable damage to the larynx and trachea but only minor vascular damage is quite often observed, which can also result in a prolonged ability to act. In some cases, the unsuccessful attempt to commit suicide by cuts to the neck may prompt the individual to inflict injuries to other body regions or to apply a second suicide method (e.g., jump from a height; complex suicide).

Even stabs to the heart are usually not associated with immediate incapacitation. Especially with short lesions of the left ventricle, the ability to act is often retained for several minutes. After 2–3-mm-long perforations of the endocardium, the ability to act was reported to continue for several hours due to slow loss of blood. Occasionally, histomorphological signs of wound healing such as deposition of fibrin and granulocytic infiltration along the track of the stab injury can be demonstrated.

Pulmonary or abdominal injuries normally do not result in immediate incapacitation.

Glossary

Acute kidney injury (AKI) Clinical syndrome involving a rapid loss of kidney function from various causes, including hypovolemia, nephrotoxic substances, and obstruction of the urinary tract, often occurring as part of multiple organ dysfunction syndrome (MODS); earlier terminology was acute renal failure (ARF).

Acute lung injury (ALI) A diffuse heterogeneous lung injury characterized by hypoxemia, noncardiogenic pulmonary edema, low-lung compliance, and widespread capillary leakage; a less severe form of acute respiratory distress syndrome (ARDS).

Acute respiratory distress syndrome (ARDS) A clinical syndrome with diagnostic criteria, presenting with severe dyspnea of acute onset, hypoxemia, and bilateral infiltrates consistent with pulmonary edema on a chest radiograph, without evidence of a cardiac cause (left atrial hypertension), arising from diffuse lung injury, either directly as the immediate result of an insult or indirectly as the consequence secondary to a remote insult.

Bacterial translocation The invasion or permeation of bacteria or bacterial products through the intestinal mucosal lining into either the lymphatics or the visceral circulation due to an impaired mucosal barrier, leading to toxemia followed by immune response activation.

Burn shock A specific form of shock arising from severe injury by heat, involving a unique combination of hypovolemic and distributive shock, accompanied by cardiogenic shock; the main feature is severe hypovolemia and massive edema resulting from rapid loss of plasma into the interstitium in the burn region.

Cardiogenic shock A form of shock resulting from cardiac pump failure due to serious heart disease or trauma, for example, myocardial infarction and cardiac contusion.

Compartment syndrome A condition involving edema or bleeding in the skeletal muscle compartment covered by the fascia, resulting in elevated pressure in the confined anatomic space and subsequent compression of muscles, blood vessels, and nerves.

Crush syndrome A condition involving release of the limbs or trunk and pelvis after a prolonged period of compression, leading to rhabdomyolysis and subsequent renal failure.

Cytokine storm Uncontrolled immune response, caused by disruption of the homeostasis of the inflammatory process as a result of the overwhelming production of cytokines.

Cytokines Hormone-like, low-molecular-weight proteins, which are secreted by various cells, including macrophages, lymphocytes, mast cells, endothelial cells, and fibroblasts, and regulate the intensity and duration of the immune response, and mediate cell-to-cell interaction, including interleukin, interferon, lymphokine, and chemokine.

Disseminated intravascular coagulation (DIC) A hemorrhagic clinical syndrome, characterized by widespread intravascular clotting and consequent systemic bleeding, as the result of disturbed balance between coagulation and fibrinolysis in the systemic circulation. Widespread intravascular clotting compromises tissue perfusion, leading to multiple organ dysfunction.

Distributive shock A form of shock due to inappropriate pooling of peripheral blood in dilated venous beds and decreased blood perfusion of other organs.

Hemorrhagic shock A form of hypovolemic shock, involving reduced circulatory blood volume due to massive hemorrhage.

Hypovolemic shock A form of shock due to reduced circulatory blood volume, subclassified into hemorrhagic and nonhemorrhagic forms. The heart cannot pump enough blood to the body because of marked loss of circulating blood volume.

Inflammatory mediator A spectrum of substances released from cells that regulates or causes inflammatory processes: chemokines, usually composed of 8–10- kDa polypeptide cytokines that are chemokinetic and chemotactic, stimulating leukocyte movement and attraction.

Local vitality Local vital reaction or biological reactivity at the sites of insult.

Multiple organ dysfunction syndrome (MODS) A clinical condition defined as the presence of altered organ function, usually involving two or more organ systems, in an acutely ill patient such that homeostasis cannot be maintained without intervention, describing the process as a continuum of physiological derangement (dysfunction) that changes over time, instead of earlier terminology such as multiple organ failure (MOF) and multisystem organ failure (MSOF).

Neurogenic shock Systemic neural paralysis, for example, spinal cord injury above the upper thoracic level, presents with a form of distributive shock due to inappropriate pooling of peripheral blood in denervated venous beds and decreased blood perfusion of other organs.

Obstructive shock A form of shock caused by obstruction of blood flow, for example, hemopericardium from cardiac or aortic rupture compresses the heart (cardiac tamponade) and diminishes cardiac output, accompanied by increased central venous pressure and decreased pulmonary arterial pressure, thus causing obstructive shock.

Oxidant The substance that is reduced and therefore oxidizes other components, for example, superoxide, nitric acid, and peroxidized lipids.

Sepsis Systemic inflammatory response syndrome (SIRS) as the result of a confirmed infectious process; this is different from 'bacteremia,' which merely implies the presence of viable bacteria in the blood.

Shock A complex syndrome resulting in inadequate tissue perfusion and cellular oxygenation, which may be caused by either systemic hypotension or disturbed blood distribution.

Stress response Stress due to various physical and mental insults induces local responses in cells at the sites of insult as well as systemic responses, involving neurogenic reactions and humoral responses in the hypothalamic–pituitary–adrenal axis.

Stress ulcer Gastric or duodenal ulcer in patients with extensive superficial burns (Curling ulcer), intracranial lesions (Cushing ulcer), or severe bodily injury.

Systemic inflammatory response syndrome (SIRS) A clinical concept that implies a systemic inflammatory process arising from a variety of severe insults, including infection and noninfectious causes. The systemic response is termed ‘sepsis’ when it is the result of a confirmed infectious process.

Traumatic shock A conventional term indicating shock arising from traumas in a broad sense but is of practical benefit to explain complex systemic dysfunction following multiple traumas, where the pathophysiology cannot be attributed to a specific category of shock.

Introduction

Traumas cause various systemic responses apart from local damage at the sites of insult, leading to death, in three phases: (1) immediate responses or deterioration characteristic of the respective trauma, (2) responses secondary to trauma in the early phase, and (3) delayed complications, sequela, or debilitation. The second-phase responses include trauma-induced shock, and further serious conditions, including systemic inflammatory response syndrome (SIRS) and sepsis, multiple organ dysfunction syndrome (MODS), and related morbidity involving coagulopathy and characteristic organ damage. These are mostly related to death in hospital and are primarily clinical concepts with definitions in the context of intensive care to prevent death and predict prognosis; however, relevant evaluation is needed in postmortem investigation, using pathology, biochemistry, and molecular pathology.

Systemic Responses Immediately Caused by Traumas

Pathophysiology and Clinical Manifestation

Severe traumas can immediately cause rapid deterioration of the whole body function, involving systemic ischemia due to blood loss from injury to major vessels or viscera, general hypoxia due to mechanical asphyxiation, functional derangement due to intoxication and thermal hazards (hyperthermia and hypothermia), possible neurogenic shock due to massive blunt force, or extreme heat or cold, and other dysfunctions, for example, due to electrocution and barotraumas. Such extreme traumas may result in cardiopulmonary arrest and death before clinical intervention (prehospital death), or may be untreatable in hospital; the death is unpreventable. In the latter cases, systemic dysfunctions due to traumas present with the relevant clinical symptoms and signs of diagnostic significance.

Postmortem Findings

At autopsy, the pathology of traumas may be usually apparent; however, the morphology is otherwise mostly unspecific, showing classic signs of acute death, as well as anemia in hemorrhagic death or congestion and/or edema in other deaths; therefore, the assessment of local vitality in response to an insult and systemic responses is important to establish a

causal relationship between the trauma and death. In these cases, postmortem biochemistry can detect extreme stress responses to fatal insults, as demonstrated by catecholamine and serotonin measurements in blood, body fluids and/or urine, and life-threatening organ damage using tissue-specific biomarkers, which are partly characteristic of respective traumas. Ubiquitinimmunohistochemistry of the midbrain is a possible indicator of neuronal stress response.

Shock: A Systemic Response to Traumas in Acute Phase

General Aspect

Shock involves complex clinical conditions in critically ill patients and can be defined as a complex syndrome resulting in inadequate tissue perfusion and cellular oxygenation, which may be caused by either systemic hypotension or disturbed blood distribution. Hypoperfusion leads to tissue hypoxia and further pathophysiology, causing multiple organ damage and dysfunction, and death ultimately, depending on the severity and duration; tissue hypoxia induces complex physiological changes, involving reperfusion injury, leading to local vasoconstriction, thrombosis, impaired perfusion, release of oxidants, and direct damage to cells, followed by activation of neutrophils and release of cytokines. This complex syndrome can clinically be categorized into (1) hypovolemic, (2) obstructive, (3) cardiogenic, and (4) distributive shock. Hypovolemic shock is subclassified into hemorrhagic and nonhemorrhagic forms, and includes ‘traumatic shock’ and ‘burn shock’ from practical aspects with reference to the respective etiologies. In forensic casework, assessment of postmortem findings related to the individual characteristics of shock with regard to trauma is needed to establish the cause and process of death.

Hemorrhagic Shock

Pathophysiology and clinical manifestation

After injury to vessels or viscera, reduced circulatory blood volume (hypovolemia) due to hemorrhage first induces compensatory sympathetic cardiovascular responses, involving vasoconstriction to divert blood from the skin, skeletal muscles, and other viscera and to enhance venous return, followed by neurohumoral reactions 10–60 min later, involving activation

of the renin–angiotensin system and release of vasopressin to promote vasoconstriction as well as sodium and water retention. Clinical manifestations substantially differ depending on bleeding velocity; tachycardia alone may be apparent before the sudden appearance of hypotension in gradual blood loss up to 30% (about 1500 ml in adults). In parallel, tissue hypoxia due to hypoperfusion initiates the inflammatory process, thus causing multiple organ damage and dysfunction, and ultimately death.

Postmortem findings

All viscera are mostly anemic in acute death, often without involvement of the brain and/or renal medulla, suggesting disturbed blood distribution in the death process; hematological or biochemical changes are usually not evident. Subacute fatalities show anemic and edematous viscera with a decreased blood erythrocyte count, hypoproteinemia in biochemistry with possible elevation of serum erythropoietin, and the increased permeability of microvascular endothelia, damage to extracellular matrix and endothelial tight junctions, and inflammatory responses in molecular pathology of the lung.

Traumatic Shock

Pathophysiology and clinical manifestation

'Traumatic shock' is a conventional term indicating shock arising from traumas in a broad sense but is of practical benefit to explain complex systemic dysfunction following multiple traumas, where the pathophysiology cannot be attributed to a specific category of shock. Traumas involving multiple viscera cause complex systemic dysfunction resulting from the combined effect of impaired cardiovascular, respiratory, and/or central nervous systems, mainly including hypovolemia due to hemorrhage and plasma extravasation into the interstitial component (third spacing) in most cases, possibly accompanied by cardiac pump failure because of cardiac contusion, hemopericardium, tension pneumothorax or air embolism, respiratory distress due to chest injury, and/or vasodilatation due to autonomic dysfunction caused by brain or cervical-upper thoracic spinal cord injury, as well as sepsis in the later phase. In addition, release of the limbs or trunk and pelvis after a prolonged period of compression causes rhabdomyolysis and subsequent renal failure (crush syndrome), and advanced skeletal muscle edema results in similar renal failure (compartment syndrome), presenting with a shocklike status.

The main pathophysiology results from tissue hypoxia due to hypoperfusion, which initiates the inflammatory process, leading to multiple organ damage and dysfunction, as in hemorrhagic shock; however, primary organ injuries aggravate systemic deterioration more seriously.

Postmortem findings

'Traumatic shock' due to multiple trauma, defined in a narrow sense, presents with general findings similar to those of subacute death from hemorrhagic shock, without any isolated trauma that can explain fatal hemorrhage or other forms of fatal shock. Hematological and biochemical findings are similar to those of hemorrhagic shock, but involve inflammatory responses.

Burn Shock

Pathophysiology and clinical manifestation

'Burn shock' is a specific form arising from severe injury by heat. The severity generally depends on the depth and extent of the burn; mortality is high when more than 20–30% of the body surface area is involved, especially in children and elderly people, and increases by complication of inhalation injury involving airway burns. Burn shock is a unique combination of hypovolemic and distributive shock, accompanied by cardiogenic shock. Burns initially causes capillary leakage syndrome as below, resulting in severe hypovolemia and massive edema (increased interstitial fluid). The shock is easily aggravated by infection, leading to SIRS and sepsis. Cardiac output is reduced as the combined result of hypovolemia, increased ventricular afterload, and decreased contractility, possibly affected by circulating mediators and impaired calcium transport in the myocardium.

In the burn region, damage to the microvasculature causes rapid loss of plasma into the interstitium. The circulation ceases within minutes to hours, and the capillaries are packed with erythrocytes and microthrombi, aggravating the inflammatory process. Edema in the burn region becomes maximal after 24 h. The cellular damage is potentially reversible, but the injury to the microcirculation is progressive over 48 h (shock phase), involving inflammatory processes with the release of vasoactive substances; the inflammatory response in the zone of stasis is responsible for burn edema and shock in this period. The systemic microcirculation immediately loses vessel wall integrity, allowing the escape of plasma proteins into the interstitium, thus resulting in precipitous decrease of intravascular colloid osmotic pressure and subsequent loss of fluid from the circulatory system; the change in fluid distribution in each compartment is marked with increased intracellular and interstitial volumes at the expense of plasma and blood volume. These cause hypovolemia with hemoconcentration, massive edema, decreased urine output, and cardiovascular dysfunction. Consequently, the combined effect of systemic microvascular damage, massive edema with impaired lymphatic drainage, and reduced cardiac output impair tissue perfusion and oxygen delivery.

Postmortem findings

In prolonged death after critical care, edema is evident in the whole body, especially in the burn region, and whole viscera are markedly edematous. Postmortem biochemistry demonstrates the terminal features of burn shock, including hypoproteinemia, elevated blood urea nitrogen and creatinine due to renal failure, hypocalcemia due to skeletal muscle damage, elevated serum C-reactive protein (CRP) and neopterin as signs of an advanced inflammatory process, and elevated serum erythropoietin, suggesting prolonged tissue hypoxia. In earlier death, hemolysis with erythrocyte fragmentation is detected as a sign of deep burns. In molecular pathology, endogenous inflammatory mediators involved in the pathogenesis of burn shock include interleukins, histamine, serotonin, oxidants, and eicosanoids. Severe burns trigger circulating mediators, for example, tumor necrosis factor (TNF)- α , interleukins, and interferon- γ , ultimately resulting in SIRS and MODS.

Other Shock Specific to Isolated Trauma

Apart from hypovolemic shock arising from massive hemorrhage or tissue damage, isolated single traumas result in specific forms of shock, characteristic of the respective visceral injuries. For instance, cardiac contusion involving pump failure causes cardiogenic shock, resulting in hypoperfusion and subsequent multiple organ dysfunction; the typical hemodynamic profile of left-sided heart failure includes decreased cardiac output accompanied by elevated pulmonary arterial and pulmonary capillary wedge pressures (left atrial hypertension) and systemic hypotension, while right-sided heart failure involves elevated right ventricular diastolic pressure with decreased pulmonary arterial pressure. Cardiac or aortic rupture may cause hemopericardium, which compresses the heart (cardiac tamponade) and diminishes cardiac output, accompanied by jugular venous distention with increased central venous pressure and decreased pulmonary arterial pressure, thus causing obstructive shock. Venous air embolism and tension pneumothorax, involving disturbed venous return, may also diminish pulmonary arterial blood flow. Neurogenic shock in spinal cord injury above the upper thoracic level presents with a form of distributive shock due to inappropriate pooling of peripheral blood in denervated venous beds and decreased blood perfusion of other organs. In postmortem investigations, these fatal outcomes should be assessed with reference to individual traumas by comprehensive analysis of autopsy findings.

Advanced Systemic Responses to Traumas in Early Phase

General Aspect

In the early phase after trauma, the respective local and systemic tissue damage due to the insult and subsequent general hypoxia resulting from hypoperfusion (shock) activates systemic inflammatory processes, leading to further deterioration of the general condition; the pathophysiology includes SIRS and sepsis, and MODS in the context of clinical management, combined with coagulopathy and damage to life-supporting organs, ultimately resulting in death. Characteristic pathologies include disseminated intravascular coagulation (DIC); acute respiratory distress syndrome (ARDS); and acute kidney injury (AKI); and the brain, liver, and gastrointestinal tract are also frequently involved.

SIRS and Sepsis

Concept and definition

SIRS is a clinical concept that implies a systemic inflammatory process arising from a variety of severe insults, including infection and noninfectious causes. The systemic response is termed 'sepsis' when it is the result of a confirmed infectious process; however, this is different from 'bacteremia,' which merely implies the presence of viable bacteria in the blood. The clinical diagnostic criteria to define SIRS consist of two or more coexisting conditions: (1) fever or hypothermia (body temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$), (2) tachycardia (heart rate >90 beats/min), (3) tachypnea (respiratory rate >20 breaths/min)

or low PaCO_2 (<32 mm Hg), and (4) an abnormal leukocyte count ($>12\,000/\text{cu mm}$ or $<4000/\text{cu mm}$, or $>10\%$ immature, band forms); however, postmortem investigation can demonstrate relevant morphological and biochemical findings.

Pathophysiology and clinical manifestation

The pathophysiology of SIRS consists of common elements, independent of the initiating insult, with partial differences. The process may be divided into three stages: (1) initiation of the inflammatory process at the primary injury site, involving the production of cytokines to promote repair, (2) release of some local cytokines into the systemic circulation to activate remote tissue-protective and repair-promoting systems, including the hypothalamic-pituitary-adrenal axis, and to recruit macrophages and platelets, under the control of suppression of proinflammatory mediators and the release of endogenous antagonists, and (3) disruption of the homeostasis of the inflammatory process as the result of overwhelming production of cytokines, leading to a 'cytokine storm' (uncontrolled immune response). Bacterial infection is a major factor that exaggerates the final stage of SIRS; bacterial endotoxins and exotoxins are potent initiators of the inflammatory cascade. Consequently, the initiation of numerous humoral cascades and the reticular endothelial system activates coagulation and complement cascades, causing coagulopathy and vascular endothelial damage involving microvascular thrombosis, vasodilatation, and increased vascular permeability, leading to loss of circulatory integrity and end organ dysfunction ultimately.

The molecular basis of SIRS involves complex multisystem interactions mediated by various cells, including macrophages, monocytes, mast cells, platelets, and endothelial cells. The tissue necrosis factor (TNF)- α and interleukin (IL)-1 are first released within 1 h of an insult and activate further inflammatory cascades modulated by transcription factors such as nuclear factor (NF)- κB , which is activated by various stimuli, including TNF- α and IL-1, as well as bacterial toxins, oxidants, and other physical and chemical stressors. IL-6, IL-8, and interferon γ are the primary proinflammatory mediators induced by NF- κB . IL-6 stimulates the release of acute phase reactants, including CRP and procalcitonin; measurements of CRP, IL-6, IL-8, and procalcitonin are included in routine diagnostic laboratory analyses.

Among the clinical criteria of SIRS, the respiratory rate is the most sensitive marker of the severity of illness, and hypotension is indicative of a serious condition involving sepsis and/or severe dehydration; however, careful consideration is needed for patients of extreme age (infants and the elderly), who may not present with typical manifestations.

Postmortem findings

It is apparently not possible to evaluate the physical parameters mentioned in clinical criteria at autopsy; however, macromorphology of the edematous viscera represents organ dysfunction in protracted death under deteriorating vitality after trauma; MODS is mostly involved in the terminal death process. The histology demonstrates the overall inflammatory cell infiltration involving activated neutrophils and macrophages in life-supporting organs (heart, lung, liver, kidney, and brain),

indicating systemic inflammation in response to trauma, and bacterial colonies in sepsis. Postmortem microbiology detects the responsible bacteria in the blood, which coincide with the histology. Biochemical markers of inflammation and immune disorder, including serum CRP and neopterin, are useful to demonstrate advanced inflammatory responses with reference to clinical findings. A spectrum of cytokines is a possible marker in postmortem biochemistry and molecular pathology. In addition, MODS as the terminal status can be assessed by biochemistry, as described below.

Multiple Organ Dysfunction Syndrome

Concept and definition

MODS is clinically defined as the presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention. It usually involves two or more organ systems; respiratory distress is most common, followed by hepatic damage, gastrointestinal bleeding, and renal dysfunction. This term was introduced to describe the process as a continuum of physiological derangement (dysfunction) that changes over time, and earlier terminologies such as multiple organ failure (MOF) and multisystem organ failure (MSOF) are no longer used clinically.

Pathophysiology and clinical manifestation

MODS is classified into two forms with a continuum, including (1) the direct result immediately arising from an insult in the relatively early phase (primary MODS) and (2) the consequence of advanced SIRS following an insult (secondary MODS). Primary MODS develops after several specific traumas, which can cause severe systemic tissue ischemia, hypoxia, or inflammation, for example, asphyxiation, pulmonary contusion, crush syndrome, and hyperthermia. Secondary MODS usually appears after an interval following an insult and represents the end stage of SIRS, commonly involving sepsis; the onset and progression of systemic inflammatory response are more evident than in primary MODS.

Theoretical pathogenesis involves (1) bacterial translocation in the intestine because of increased permeability and altered immune function of mucosae, resulting from hypoperfusion and subsequent ischemia, enhanced by hepatic dysfunction, leading to toxemia followed by immune response activation (gut hypothesis), (2) contribution of endotoxin following Gram-negative bacterial infection, leading to macrophage activation (endotoxin-macrophage hypothesis), (3) hypoxia-induced tissue damage due to protracted hypoperfusion, accompanied by microvascular thrombosis (tissue hypoxia-microvascular hypothesis), (4) contribution of a second insult in the presence of an innate immune system primed by injury (two-event theory), and (5) combined effect of these mechanisms (integrated hypothesis).

The clinical course is stratified into four stages (Sepsis-Related Organ Failure Assessment Scoring System, SOFA; the European Society of Intensive Care Medicine), scoring the physiological measures of dysfunction in six organ systems (respiration, coagulation, liver, cardiovascular, central nervous system, renal): (1) increased volume requirements and mild respiratory alkalosis, accompanied by oliguria, hyperglycemia, and increased insulin requirements, (2) tachypnea, hypocapnea,

and hypoxemia with moderate liver dysfunction and possible hematological abnormalities, (3) shock with azotemia and acid-base disturbances with significant coagulation abnormalities, and (4) vasopressor dependence with oliguria or anuria, followed by ischemic colitis and lactic acidosis. ARDS and AKI are frequent complications.

Postmortem findings

Macropathology of MODS includes general edema, overall cloudy swelling of viscera with multiple hemorrhages, congested lungs with pleural effusion, brain softening, and multiple hemorrhages or erosions of gastrointestinal mucosae. The histology demonstrates hyaline membranes of the lungs with complication of pneumonia; focal necrosis in the heart, liver, kidney, and spleen; and microvascular thrombosis with accumulation of neutrophils and platelets. Centrilobular necrosis of the liver represents profound hypoperfusion.

Immunohistochemistry demonstrates abnormal pulmonary surfactant distribution in lungs, representing the stage and severity of ARDS, increased thrombomodulin expression in vascular endothelia, suggesting dysfunctional coagulation, activated neutrophils and macrophages involved in SIRS, and brain and myocardial injury.

Postmortem biochemistry demonstrates advanced hypoproteinemia, hypoalbuminemia, and hypocholesteremia representing a serious general condition. Tissue-specific serum biomarkers to detect organ damage or dysfunction include pulmonary surfactants, myocardial markers, bilirubin, and cholinesterase as indicators of liver function, nonprotein nitrogen for renal dysfunction, and erythropoietin as an indicator of prolonged hypoxia. Serum CRP and neopterin are useful markers of SIRS as a major cause of MODS.

Disseminated Intravascular Coagulation

Pathophysiology and clinical manifestation

DIC is a clinical syndrome, which is a relatively common coagulopathy, characterized by widespread intravascular clotting and consequent systemic bleeding as the result of disturbed balance between coagulation and fibrinolysis in the systemic circulation by pathological processes. The pathogenesis involves (1) abnormal clotting sequence involving consumption of platelets and coagulation factors, triggered by tissue injury or intravascular disorders; (2) uncontrolled thrombin formation overwhelming the inhibitor system, accompanied by acceleration of the coagulation process; (3) subsequent fibrin deposition in small- and mid-sized vessels of multiple organs; (4) abnormal fibrinolysis by plasmin with impaired physiological anticoagulant mechanisms involving thrombin formation; (5) release of fibrin degradation products, affecting platelet function and inhibiting fibrin polymerization; and (6) decreased coagulation inhibition level. Widespread intravascular clotting compromises tissue perfusion, especially in lungs, kidney, liver, and brain, leading to multiple organ dysfunction. In these processes, several proinflammatory cytokines such as TNF- α and IL-6 play key roles in mediating coagulation disorders by the expression and release of tissue factor (a transmembrane glycoprotein) in endothelial cells and monocytes, with a close relationship to

SIRS. The expression of tissue factor also depends on P-selectin in the venules, which is induced by soft-tissue injury. DIC develops either as the immediate direct result of intravascular disorders such as amniotic fluid embolism, fat embolism, acute hemolytic transfusion reaction, and snake or insect envenomation, leading to SIRS, or as part of SIRS arising from other insults, in accordance with the severity of the originating insult; however, hypoxia or ischemia alone can change coagulation and fibrinolysis through multiple pathways.

The consequence is life threatening; DIC is most often encountered in the critical care setting. Clinical manifestations are varied, depending on the severity of impaired hemostasis and underlying conditions. The most common findings are bleeding ranging from oozing at venipuncture sites, petechiae, and ecchymoses on the skin to severe bleeding in the gastrointestinal tract, lungs, and brain. The diagnosis is based on clinical signs of bleeding tendency and laboratory findings, including thrombocytopenia, erythrocyte fragmentation, prolonged coagulation time, and fibrin degradation products (D-dimer).

Postmortem findings

Macropathology typically presents with multiple petechiae and ecchymoses, and oozing at sites of clinical intervention on the skin, gastrointestinal bleeding, and overall multiple hemorrhages in the viscera, especially the lung and brain. The histology demonstrates the morphological presentation of 'DIC' as detected by multisite fibrin thrombi in capillaries and mid-sized vessels with multiple hemorrhages overall in the brain, heart, lungs, kidney, adrenal, spleen, and liver, accompanied by the findings of systemic inflammation in cases of the terminal stage of SIRS.

Acute Lung Injury and Acute Respiratory Distress Syndrome

Pathophysiology and clinical manifestation

ARDS and a less severe form of ALI are clinical syndromes with diagnostic criteria, presenting with severe dyspnea of acute onset, hypoxemia, and bilateral infiltrates consistent with pulmonary edema on a chest radiograph, without evidence of a cardiac cause (left atrial hypertension). These arise from diffuse lung injury, either directly as the immediate result of an insult (e.g., pulmonary contusion, aspiration, near drowning, and toxic/irritant gas inhalation) or indirectly as the consequence secondary to a remote insult (e.g., head trauma, multiple bone fractures, and burn).

The development of ARDS is marked by three phases with characteristic clinical and pathological features. (1) Exudative phase: In the first week following an insult, alveolar injury causes the leakage of protein-rich edema fluid in the interstitial and alveolar spaces, accompanied by activation of proinflammatory mediators such as $\text{TNF-}\alpha$ and IL-1 , inducing leukocyte infiltration and hyaline membrane formation involving aggregation of condensed plasma proteins with cellular debris and dysfunctional pulmonary surfactants, as well as microvascular injury with microthrombi and hemorrhages and fibrocellular proliferation. Edema fluid predominantly accumulates in the dependent

portions of lungs, which diminishes aeration, causing atelectasis, leading to severe hypoxemia and hypercapnea. Consequently, dyspnea develops rapidly with bilateral diffuse pulmonary infiltrates; however, mechanical ventilation can aggravate the alveolar injury. (2) Proliferative phase: During the second to third week, when not recovered, progressive lung injury develops, involving early changes of pulmonary fibrosis. Organization of alveolar exudates with lymphocyte-predominant inflammatory cell infiltration, accompanied by proliferation of type II alveolar cells. (3) Fibrotic phase: After 3–4 weeks, when the clinical course is protracted, pulmonary fibrosis develops; extensive alveolar and interstitial fibrosis disrupts lung structures, leading to emphysema-like changes with vascular occlusion, resulting in pulmonary hypertension.

Postmortem findings

The macro- and micropathology described above are detected in accordance with each phase. Immunohistochemistry and biochemistry are useful to demonstrate the inflammatory process, and alveolar injury involving dysfunction of pulmonary surfactants.

Miscellaneous

Apart from SIRS and MODS, there are several specific forms of organ damage and dysfunction caused by remote responses to trauma, which may contribute to the death process. These include fat embolism following bone fracture or soft-tissue injury; renal dysfunction due to rhabdomyolysis, typically in crush syndrome; and gastrointestinal 'stress ulcers,' especially after head injury (Cushing ulcer) and burn (Curling ulcer), and neurogenic pulmonary edema after head trauma.

Delayed Complications

Severe trauma may leave survivors with physical and mental aftereffects, leading to physical and mental disability: sequela or debilitation. In particular, severe head injury may result in seriously ill conditions affecting various organs and physical functions, including immunodeficiency, leading to opportunistic infections or shortening of life. Otherwise, immobility and inadequate water intake can cause pulmonary embolism as a cause of sudden death. Posttraumatic stress disorder (PTSD) as a psychological aftereffect may partly be attributed to dysfunction of the central nervous system in response to exposure to an extreme traumatic event.

Sudden Natural Death

A Thierauf and S Pollak, University of Freiburg, Freiburg, Germany

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Berry aneurysm The cerebral arteries, mainly those forming the Circle of Willis on the basal surface of the brain, may show focal saccular outpouchings that are prone to rupture.

Coronary heart disease (CHD) This term describes the pathophysiological consequences of severe narrowing or blockage of coronary arteries, usually caused by atherosclerosis.

Esophageal varices This term means a pathological condition characterized by an extreme dilation of submucosal veins in the lower third of the esophagus, mostly as a consequence of portal hypertension in patients with liver cirrhosis.

Pulmonary embolism A blockage of the pulmonary artery and/or its branches, mostly caused by blood clots originating from the legs in the presence of deep vein thrombosis.

Definition

The term covers the following deaths from an internal (pathological) cause:

- *sudden* death without any previous symptoms ('in complete well-being'),
- *unexpected* death after a short period of complaints not regarded as threatening.

Some authors suggest a third category, namely, death following *rapid deterioration* of a known disorder not regarded as serious.

In practice, classification of these deaths may be difficult if the individual died alone with no history to suggest a cause of death. Quite often, a sudden and/or unexpected death can be diagnosed only on the basis of the circumstances under which the deceased has been found (e.g., at the wheel of a vehicle or his workplace). The fact that no medical treatment took place in the days preceding death can also be only a hint that death came unexpectedly.

Criminalistic Aspects

When an individual dies without having presented any previous symptoms (sudden death), the medical examiner can determine neither the manner (natural/unnatural) nor the cause of death. These cases have to be categorized as 'manner of death undetermined' and can only be clarified by performing an autopsy and further examinations.

The circumstances under which death occurred, the situation at the scene, or the findings on the body may even be suggestive of the involvement of another person, such as:

- If an individual dies during an argument or in close temporal connection with an accident, a traumatic cause seems probable.
- Agonal falls or seizures sometimes cause suspicious injuries.
- Anticoagulant therapy or diseases associated with hemorrhagic diathesis may lead to multiple hematomas resembling blunt-force injuries from abuse.

- Massive external bleeding – especially if associated with extensive blood traces at the scene – is always suspicious.

In natural deaths, the following sources of bleeding are of major importance: bite marks of the tongue due to convulsions, esophageal varices, gastroduodenal ulcers, erosion of pulmonary vessels in the presence of tuberculosis or bronchial carcinoma, and spontaneous rupture of lower limb varices. Putrefactive changes and animal scavenging can be misinterpreted as vital injuries upon superficial inspection.

Sometimes, the antemortem symptoms may suggest an intoxication, for example, in spontaneous intracranial hemorrhages (ruptured berry aneurysm and nontraumatic intracerebral hemorrhage). Signs of increasing intracranial pressure, such as headache, nausea, vomiting, and coma, may be misinterpreted as symptoms of intoxication; conversely, a supposedly natural death may prove to be due to an intoxication at autopsy.

Special Categories

In *infancy*, the sudden infant death syndrome has to be differentiated from other natural and from unnatural causes, such as smothering. Even in severe internal injuries, there may be no externally visible correlate. In any case, the forensic pathologist has to look for (sometimes inconspicuous) signs of mechanical suffocation. A potential intoxication and an electric shock also have to be considered.

Deaths at the *workplace* require particularly a thorough investigation to prove or exclude harmful external effects or influences such as occupational intoxications. Electrocutation and lightning fatalities may also be overlooked at first. The electrothermal skin lesions and the corresponding damage in the clothing may be overlooked by the physician performing the external postmortem. In injuries due to a fall, the question arises whether death was due to the trauma or a preexisting disease suddenly becoming manifest and causing the individual to fall. A sudden loss of consciousness owing to an organic, vasomotor, or metabolic reason such as an epileptic seizure, aneurysmal bleeding, syncope, or hypoglycemic coma

can result in a fatal industrial accident. Determination of the blood alcohol concentration is mandatory.

Sudden death while operating a motor vehicle is mostly seen in males in their sixth and seventh decade of life. Among the causes of death, coronary artery disease ranks first and accounts for over 80% of cases. The deceased are sometimes found in properly parked cars. After the onset of the premortal symptoms, the driver may still be able to stop the car, possibly with the assistance of the front-seat passenger. Serious accidents injuring or even killing other road users occasionally occur but are comparatively rare. If recent/acute pathological findings such as coronary thrombosis, acute myocardial infarction, aneurysmal rupture, or massive cerebral bleeding are detected, the fatality can easily be classified as a natural death at autopsy. Problems arise when exclusively chronic organ changes (stenosing sclerosis of the coronary arteries and scars from former myocardial infarction) and significant injuries from an additional car collision are found side by side. Unusual driving behavior, for which observers have no explanation, may in fact be due to a natural disease but can also be attributable to the influence of alcohol or drugs; if the driver approaches an obstacle without reducing speed, a suicidal act also has to be kept in mind. Deaths in motor vehicles should always induce the forensic pathologist to determine the CO-Hb concentration in the corpse blood. Exhaust gases emitted by motor vehicles contain carbon monoxide and can be inhaled either accidentally or with suicidal intent (accidents by running a car's engine in a closed garage and suicides by conducting exhaust gases into the interior of a car, especially in the absence of a catalytic converter).

If a person dies during sports activities, the first question to be answered is whether death was caused by an (accidental) trauma or a latent pathology. Depending on the external circumstances, a heat stroke also has to be taken into consideration. Natural deaths during sports activities predominantly occur in individuals with preexisting cardiovascular diseases, especially sclerosis of the coronary arteries and its sequelae, often in combination with cardiac hypertrophy. Males are far more frequently affected than females and the highest incidence is seen in the third to fifth decade of life. Preexisting chronic pathologies, such as coronary atherosclerosis, cardiac hypertrophy, and scars from myocardial infarction, lead to a propensity for arrhythmia and heart failure. Even in the absence of acute changes, such as fresh coronary thrombosis or myocardial infarction, the abnormal physical stress due to sports activities may trigger a fatal dysfunction of the structurally damaged heart. Sudden circulatory collapse can be the first manifestation of an undiagnosed heart disease. However, a seemingly 'blank' medical history does not justify the conclusion that the underlying condition had really been without symptoms ('silent'). Many people do not talk about their stenocardiac complaints or misjudge and trivialize them. Physical fitness is no reliable indicator of a healthy cardiovascular system. Fitness and motivation do by no means rule out high-grade stenosing of the coronary arteries.

Sudden death during sexual activity often occurs under seemingly suspicious circumstances, such as when the deceased is found in a hotel room, car, or outdoors partially or completely undressed and sadomasochistically bound. Under

criminalistic aspects, one then has to distinguish between natural death, autoerotic accident, and homicide. Males in their sixth and seventh decade of life are those most at risk of dying suddenly during sexual activities, sometimes after the use of sildenafil or other erectile dysfunction remedies. The most frequent cause of death is coronary heart disease.

Classification According to the Morphological Substrate

The following survey refers to adults and children older than 1 year.

Cardiovascular Diseases

In the statistics on sudden death, cardiovascular diseases were ranking at the top as early as the beginning of the twentieth century and now they account for about 70–80% according to more recent studies. Numbers vary dependent on the composition of the autopsy material and the nationally different classification criteria. The incidence in males continues to be significantly higher than in females, although it has dropped in the last few decades. In the male population, sudden death from a cardiovascular disease is relatively common in the fourth to sixth decades already, whereas in women a higher incidence is not observed before the seventh decade.

Coronary Heart Disease

Under nosological aspects, most deaths discussed here have to be attributed to coronary heart disease. The morphological correlate is 'stenosing coronary atherosclerosis.' Arteriosclerotic vascular changes may lead to acute coronary occlusion either due to edematous swelling of an atheromatous plaque or by bleeding in the intima or – most important – by thrombotic material adhering to the inner surface of the vascular wall (Figure 1). Sites of predilection are the great subepicardial vascular trunks (left coronary artery with its anterior interventricular and circumflex branch, right coronary artery), whereas embolic coronary occlusion is rare.

Stenosing coronary atherosclerosis can cause (relative) coronary insufficiency either alone or in combination with cardiac

Figure 1 Coronary thrombosis.

hypertrophy and is able to trigger a fatal arrhythmia (asystolia or ventricular fibrillation) at any time – that is, also without any exogenous stress. Nevertheless, these cases should only be classified as natural deaths after all other potential causes such as mechanical trauma, electric shock, and intoxication have been ruled out.

Fresh myocardial necrosis (Figure 2(a) and 2(b)) need not always be discernible in acute coronary death. Sometimes, histological examination reveals only disseminated muscle fiber necrosis as evidence of a premortal coronary insufficiency. With the help of immunohistological staining, ischemic tissue lesions can be detected at an early stage already.

In 6–7% of sudden deaths from coronary heart disease, a rupture of the cardiac wall with consecutive hemopericardium

is diagnosed at autopsy. The average age of these decedents is significantly higher than in the other groups of acute cardiac death; females are overrepresented in this subgroup.

In the forensic autopsy material, infarction scars (Figure 3(a) and 3(b)) are seen more often than fresh myocardial necroses. If the inner layer of the ventricular wall is affected, parietal thrombi may form on the endocardium and break away (risk

Figure 2 Fresh myocardial necrosis. (a) Fresh necrosis (white arrow) and granulation tissue (black arrow) in the wall of the left ventricle. (b) Fresh necrosis in a papillary muscle.

Figure 3 Myocardial infarction scars. (a and b) Distinct transmural postinfarction scars of the left ventricle with formation of a chronic aneurysm.

of embolic complications). When the outer myocardial layer is involved, epistenocardic pericarditis and sometimes also adhesion between the parietal and visceral layers of the pericardium (concretio cordis) develop. Transmural necroses may result in chronic aneurysms of the cardiac wall (Figure 3(a) and 3(b)).

Nonischemic Heart Disease

From a statistical point of view, cardiac diseases without sclerotic changes of the coronary arteries play a smaller role in sudden deaths from a natural cause.

Severe hypertrophy of the myocardium always involves the risk of acute cardiac death, especially if the critical heart weight (500 g) has been surpassed. Even if the overstrain is limited to the right ventricle (cor pulmonale), unexpected and sudden death may occur.

The large group of cardiomyopathies (CMs) comprises noninflammatory myocardial diseases not associated with coronary stenosis, any organic heart defect, or hypertension in the systemic and pulmonary circulation. They are of forensic relevance because an acute arrhythmia or forward heart failure may trigger sudden cardiac death.

In primary congestive CM, the strong dilatation of all cardiac cavities is the major morphological feature. Idiopathic hypertrophic subaortic stenosis is characterized by 'asymmetrical' thickening of the ventricular septum. Alcoholic CM manifests itself in eccentric hypertrophy with a varying degree of fibrosis.

Among the inflammatory heart diseases, the different forms of myocarditis (bacterial, viral, infectious toxic, rheumatic, idiopathic, etc.) have to be emphasized. Macroscopically, the heart is mostly flaccid and dilated and its cut surface occasionally shows small pale areas; in chronic forms, the myocardium may be interspersed with small scars. Microscopically, the picture is characterized by inflammatory processes in the interstitium and degenerative changes of the muscle cells. For histological investigation, tissue samples should be taken from both atria and ventricles (including the conduction system).

Congenital and acquired heart defects as well as vascular malformations (aortic isthmus stenosis, anomalies of the coronary arteries, etc.) also have to be borne in mind as causes of sudden cardiac death. As is generally known, aortic valve

Figure 4 (Continued)

Figure 4 Aortic rupture. (a) Cardiac tamponade. (b) Aortic rupture site. (c) Dissection of the vascular wall.

stenosis with compensatory left ventricular hypertrophy involves a high risk of acute cardiac failure.

Aortic Rupture

Spontaneous aortic ruptures account for about 1.4% of sudden deaths. At autopsy, aortic ruptures often present as a spontaneous laceration or a dissection of the vascular wall. Major risk factors are systemic hypertension or a congenital weakness of the aortic wall as seen in Marfan's syndrome (cystic degeneration of the middle layer). The most common primary rupture site is in the ascending aorta or the aortic arch, and less often the thoracic or abdominal segment of the aorta. The direct cause of death is typically a cardiac tamponade due to a secondary rupture into the pericardial sac (**Figure 4(a)–4(c)**). Less often, the rupture is followed by acute bleeding into one of the thoracic cavities.

Arteriosclerotic aortic aneurysms (**Figure 5**) mostly rupture – corresponding to the infrarenal site of predilection – into the retroperitoneal space or the abdominal cavity or, if located in the thorax, into the mediastinum and one of the pleural cavities.

The incidence of luetic aneurysms has strongly declined in the past few decades.

Pulmonary Embolism

The significance of pulmonary embolism (**Figure 6(a)**) as a cause of sudden death is assessed differently. In clinical

pathology, postoperative pulmonary artery embolism and embolism associated with clinically manifest leg and/or pelvic deep vein thrombosis (**Figure 6(b)**) are predominant. Forensic pathologists see acute fatalities from pulmonary embolism also without any previous symptoms of thrombosis in seemingly healthy persons who die during routine activities such as climbing stairs.

This type of 'spontaneous' thromboembolism is observed especially in older women; in premenopausal women, a potential relation with hormonal contraception has to be kept in mind. Usually, the deep veins of one or both legs still contain residual thrombi; the pelvic veins alone are rarely the origin of acutely lethal pulmonary embolism.

Posttraumatic pulmonary embolism is a sequel of the preceding injury. It should therefore not be classified as a natural death.

Diseases of the Respiratory Tract

Apart from cardiovascular diseases, the various forms of pneumonia are the most common cause of unexpected death. This may come as a surprise, as pneumonia is usually associated with impressive symptoms. However, sometimes there is a striking discrepancy between the subjective feeling and the objective findings.

A considerable part of untreated pneumonias ending in sudden death concerns persons from marginal social groups

Figure 5 Arteriosclerotic aortic aneurysm.

Figure 6 Pulmonary embolism. (a) Embolized thrombi in the central pulmonary arteries. (b) Deep vein thrombosis.

(homeless people and alcoholics). In persons living alone and found dead in their flat, it is hardly possible to find out in retrospect whether, and if so, how long they had suffered from manifest symptoms.

Focal pneumonia (bronchopneumonia) diagnosed only at autopsy may occur as a consequence of a preceding intoxication (alcohol, psychotropic drugs, narcotics, and carbon monoxide); toxicological analyses should therefore be mandatory, especially in aspiration pneumonia.

Most focal pneumonias originate from the initially affected bronchi, often due to a bacterial superinfection following a viral infection. Since the 1970s, the spectrum of microorganisms causing bacterial pneumonia has been extended by *Legionella pneumophila*.

In the forensic autopsy material, lobar pneumonia accounts for a surprisingly high percentage of inflammatory pulmonary diseases (Figure 7). Individuals whose immune system is impaired (e.g., after chronic alcohol abuse or exposure to cold) are particularly at risk.

Tuberculosis is now less common in developed countries. However, although its morbidity and mortality have dropped, deaths from untreated tuberculosis are still observed. By

detecting unknown sources of infection, forensic pathologists help to further eliminate tuberculosis as an endemic infectious disease.

Pulmonary tuberculosis manifests itself in exsudative and/or productive changes; the additional presence of fibrous or calcified residues suggests that an old tuberculous focus was reactivated due to reduced resistance. In cavernous forms of pulmonary tuberculosis, massive hemoptysis (hemorrhage) occasionally leads to rapid death.

In influenza infections, primary hemorrhagic pneumonia may result in peracute death. Apart from pulmonary changes such as focal hemorrhages and hemorrhagic edema, the dark red discoloration of the tracheal and bronchial mucosa is a characteristic finding.

Among the noninfectious pulmonary diseases, bronchial asthma has to be mentioned as a potential cause of unexpected death. At autopsy, obstructive pulmonary emphysema and copious, viscous mucus in the deep respiratory tract are found. Histologically, characteristic signs are mucous obstruction of the bronchi, Curschmann's spirals and Charcot-Leyden crystals, an increased number of beaker cells, infiltration of the tunica propria with eosinophil granulocytes, and thickening of the basal membrane.

Patients with central bronchial carcinoma may die unexpectedly due to erosion of a pulmonary vessel with subsequent hemoptysis and blood aspiration.

Figure 7 Lobar pneumonia.

Gastrointestinal Diseases

Most esophageal varices (Figure 8(a)) develop due to portal hypertension, with liver cirrhosis (Figure 8(b)) being the best-known and most important cause.

The subepithelial veins at the lower end of the esophagus are most prone to rupture. The risk of a fatal hemorrhage is especially high in patients with cirrhosis because they often have also a coagulation defect. As a result of the terminal hematemesis, blood will be found around the mouth (Figure 8(c)) and at the scene.

Sparse postmortem lividity may suggest blood loss already before autopsy. The organs are strikingly pale; stomach and gastrointestinal tract contain blood looking like coffee grounds or tar. At autopsy, it is advisable to leave the esophagus connected to the stomach so that vascular lesions located near the cardia can also be identified. In the Mallory-Weiss syndrome, severe vomiting or retching may be followed by tears at the junction of the stomach and esophagus. Such lacerations are mainly seen in alcoholics and are a major cause of gastrointestinal bleeding.

In peptic ulcers of the stomach and duodenum (Figure 9), hemorrhage from arterial erosion is a potentially fatal complication. In these cases, hematemesis can also produce suspicious evidence at the scene.

Further diseases which can also cause unexpected death will only be mentioned briefly here: hemorrhagic necrotizing pancreatitis, various forms of mechanical ileus (obstruction by tumors, adhesions, hernia, volvulus, invagination, etc.), and paralytic ileus (subsequent to a perforated ulcer, occlusion of a mesenteric vessel, etc.). Most of these individuals die unobserved without prior medical treatment.

Figure 8 Bleeding of the esophageal varices. (a) Esophageal varices. (b) Liver cirrhosis (cirrhotic liver in comparison to a normal liver). (c) Blood around the mouth from terminal hematemesis.

Figure 9 Peptic ulcer of the duodenum.

Diseases of the Central Nervous System

Massive cerebral hemorrhage (Figure 10) is a dreaded complication of arterial hypertension. Apart from high blood pressure, which is regarded as the most important etiological factor, the following causes of bleeding have to be mentioned:

aneurysms, leukosis, hemorrhagic diathesis, angiomas, and tumors. When classifying massive hemorrhages according to their localization, the region of the basal ganglia is the most frequently affected part, but the pons and the cerebellum are also involved relatively often.

Figure 10 Massive cerebral hemorrhage.

Aneurysms of the basal cerebral arteries not caused by trauma are attributed to congenital, atherosclerotic, or inflammatory vascular changes. Sites of predilection are the bifurcations of the *circulus arteriosus Willisii* (**Figure 11(a)**). Accordingly, subarachnoid hemorrhages, which tend to be most pronounced in the region of the basal cisterns, are often found after ruptured berry aneurysms (**Figure 11(b)**).

Deaths of epileptics often have an unnatural cause such as craniocerebral trauma due to a fall or drowning in the bathtub. Fresh tongue bites may suggest that seizure and death occurred in quick succession; moreover, attention should be paid to soiling by stool and urine. The examination of the brain focuses on the identification of primary focal lesions (in symptomatic epilepsy) and secondary long-term damage such as cell loss and gliosis in the hippocampus. At autopsy, some deaths in people with epilepsy do not reveal any abnormalities. The term 'sudden unexpected death in epilepsy' describes a fatality from unexplained respiratory failure or cardiac arrest.

Unexpected death is occasionally seen in inflammatory diseases of the brain and its meninges. A generally known clinical picture, which occurs primarily in children, is peracute

Figure 11 Aneurysm of a basal cerebral artery. (a) Berry aneurysm of the basilar artery at its bifurcation site where the vessel divides into the posterior cerebral arteries. (b) Subarachnoid hemorrhage.

meningococcal sepsis with hemorrhages of the adrenal glands (Waterhouse–Friderichsen syndrome). Pneumococcal meningitis can also take a fulminating course.

Other Causes of Sudden Death

Among the metabolic diseases, diabetes mellitus is of special forensic relevance (death in hypo- or hyperglycemic coma).

In the presence of an (isthmic) tubal pregnancy, rupture of the fallopian tube may lead to internal exsanguination within a very short time. Eclampsia and amniotic fluid embolism are also associated with a high maternal mortality.

If a bacterial or parasitic infection is misdiagnosed as a 'trivial' disease, a fatal outcome not expected by the environment may occur (e.g., streptococcal sepsis after trivial injuries and malaria tropica after staying in an endemic territory).

Sudden Infant Death Syndrome (SIDS)

T Bajanowski, University of Duisburg-Essen, Essen, Germany

Introduction

Despite a considerable decline in its incidence, sudden infant death syndrome (SIDS) is still the leading cause of death among infants between 8 and 365 days of age in industrialized countries. In the United States, more than 4500 infants die suddenly every year, for no obvious cause. According to the CDC, half of these cases are due to SIDS. The incidence of this in the United States in 2005 was 0.54 per 1000 live births.

In addition to these SIDS cases, there are deaths of undetermined cause, and death due to accidental suffocation and strangulation in the bed or crib/cot, representing a further 0.38 per 1000 live births. The combined number of SIDS cases plus undetermined deaths and deaths due to suffocation and strangulation is 0.93 per 1000 live births. In Europe, the numbers are slightly lower. In Germany, the SIDS incidence for 2009 was 0.29, whereas in England and Wales, it was 0.38 per 1000 live births. The highest incidence is still found in New Zealand with a rate of 0.8 in 2005 and the lowest are in the Netherlands with 0.06 and Japan with 0.13 in 2007 ([Figure 1](#)).

However, the number of sudden unexplained deaths (SUDI) in the first and second years of life has not changed substantially in the last 10 years. Similar statistics have been reported by many industrialized countries.

Reduction in SIDS rates is mirrored by the commensurate reduction in postneonatal mortality. This is largely attributable to the decline in prone sleeping following studies by de Jonge and Engelberts in the Netherlands and Fleming in the United Kingdom, which found that the prone sleeping position was a major risk factor in sudden infant deaths. However, despite worldwide research, the cause or causes of sudden deaths in infancy have not yet been found.

Forensic significance of these deaths arises from the relatively high SIDS frequency, the necessity to differentiate SIDS from nonnatural causes of death in each single case ([Table 1](#)), and in particular, the fact that infants and younger children constitute a special group of victims. The intensity of violence causing injury may be smaller compared to adults. Certain types of violence can be observed (e.g., shaken baby syndrome), and infants also display certain types of injury (e.g., greenstick fracture).

Definition

The term sudden and unexpected death in infancy refers to the proportion of infant deaths occurring more or less suddenly and unexpectedly. SUDI was defined by Huber in 1992. The postmortem examination, which should ideally include a history of gestation, delivery and postnatal development, a death

scene investigation, a psychosocial family history, a complete autopsy, and a confidential case conference may:

- reveal changes that alone – or in combination – sufficiently constitute the cause of death (non-SIDS);
- reveal changes that even when clearly present are not sufficient to explain the death ('borderline' SIDS); and
- fail to demonstrate any abnormalities (SIDS).

This means that SUDI is the most heterogeneous group, as it includes all categories of sudden and unexpected infant deaths.

In comparison, the term SIDS describes deaths that occur within the first year of life during sleep or in association with sleep. The first definition was introduced by Beckwith in 1969 who combined this typical phenomenology with the autopsy results: 'the sudden death of any infant or young child, which is unexpected by history, and in which a thorough postmortem examination fails to demonstrate an adequate cause of death'. Since that time, the definition has been the subject of controversy and the application of the definition has shown wide variation from country to country and from researcher to researcher, leading to an inconsistent use on death certificates and for research. In 1989, the Seattle definition was introduced by a panel of experts (NICHD definition), and the term 'thorough postmortem examination' was defined more precisely. Furthermore, 'the examination of the death scene, complete autopsy, and review of the clinical history' were introduced. In the 1990s, various authors proposed and used different subclassifications of SIDS for scientific investigations. As a result of Beckwith's call for reexamination of the definition, an expert group proposed a new definition in 2004 (San Diego definition). A more general definition was agreed upon, to be used for certification purposes and in general epidemiological studies, together with a subclassification based on specific epidemiological features and the amount of information available from other sources.

According to the San Diego definition of SIDS, this diagnosis can be made only if 'an infant under one year of age has died suddenly and unexpectedly, the onset of the fatal episode was apparently associated with sleep, and a thorough investigation of the case, including performance of a complete autopsy and review of the circumstances of death and the clinical history does not provide an explanation for the death.' If these criteria are not fulfilled, the cases should be termed 'unclassified infant death' (USID) or 'sudden unexpected death in infancy' (SUDI).

The stratified section of the San Diego definition may be applied in scientific investigations of SIDS cases. There are three subtypes of SIDS, which rely on 30 different pieces of information from specific investigations, such as the autopsy findings (including additional investigations), death scene investigation, and clinical history ([Table 2](#)).

Figure 1 Incidence of SIDS in selected countries between 1990 and 2005.

Table 1 Causes of sudden unexpected death in infancy

Natural causes of death	Unnatural death
SIDS	Suffocation by
Infection	● Soft covering
● Various types of pneumonia	● Occlusion of mouth and nose
● Meningoencephalitis	● Chest compression
● Gastroenteritis	● Aspiration of stomach contents
● Myocarditis	
● Septicaemia	
Metabolic diseases	Shaken baby syndrome
● Disturbances of fatty acid oxidation	Poisoning
● Pyruvate dehydrogenase deficiency	Other types (masked) of blunt trauma
● Biotinidase deficiency	Munchausen syndrome by proxy
● Hyperinsulinism	Neglect
● Disturbances of thiamine metabolism	Hyperthermia of external causes
Malformation	
● Blood vessels	
● Cardiac malformation	
● Fibroelastosis of the myocardium	
● Pierre Robin sequence	
Reye syndrome	
Hyperthermia from natural causes	
Dysplasia of lungs	

Epidemiology and Risk Factors

SIDS is a rare event in the first month of life. Most SIDS victims die between the second and fifth months of life and 60% are male.

Since the epidemiological studies in the late 1980s and early 1990s, a number of important risk factors for SIDS have been identified. The most widely recognized risk factor is the prone sleeping position. Since then, many countries have begun encouraging parents to avoid this sleeping position and to place infants on their back. The prevalence of infants sleeping prone has since decreased by 50–90% in most countries and the rate of SIDS has decreased proportionately by 50–90%. The side sleeping position is also discouraged, as it is unstable and infants placed on their side will subsequently roll to a prone position.

There used to be a peak of deaths in the winter months, due to the prevalence of upper respiratory tract infections. But since the decline in prone sleeping this winter, that peak has disappeared. In all epidemiological studies, maternal smoking during pregnancy emerged as an important risk factor in SIDS. Although postnatal smoking is also a risk factor, it is difficult to isolate this from prenatal smoking. If all smoke exposure could be eliminated, it is highly likely that one-third of SIDS cases could be prevented.

Since the decrease in prone sleeping, other risk factors have become apparent, such as an unsafe sleeping environment. Soft or loose bedding, pillows, quilts, and sheepskins have been identified as risk factors in SIDS. Additional risk factors are warmer room temperatures or multiple layers of clothing. Quilts and loose bedding increase not only the risk of smothering, but also overheating.

Sharing the parental bed with an infant facilitates breastfeeding and promotes parent–infant bonding. However, epidemiological studies have shown that bed sharing constitutes an increased risk mainly when the parents are smokers or the infant is very young (under the age of 12 weeks). Bed sharing on a sofa is always dangerous and should always be avoided.

Case–control studies have shown that using a dummy reduces the risk of SIDS, and a recent meta-analysis has shown a strong protective effect. Results from many studies, including a recent meta-analysis, have demonstrated the protective effect of breastfeeding against SIDS. Immunizations in infancy are often seen by lay people as a risk factor. A couple of studies have confirmed the protective effect of immunizations in infancy (Table 3).

Results of Autopsy

Investigation of cases of sudden and unexpected deaths in all age groups is one of the major fields of forensic medicine. The investigation of infant deaths requires the application of special diagnostic methods and includes forensic pathology as well as other fields of forensic medicine and medicine in general, for example, radiology, toxicology, microbiology, virology, neuropathology, pediatric pathology, pediatrics, clinical chemistry, physiology, epidemiology, and genetics. An autopsy seeks to achieve five main aims:

1. Determining the manner of death (natural/unnatural)
2. Diagnosing the cause of death
3. Deducing whether or not the death would have been preventable

Table 2 Criteria used in the San Diego definition of SIDS

	<i>Previous history</i>	<i>Circumstances of death</i>	<i>Autopsy findings</i>
General definition	● Sudden und unexpected death ● Under 1 year of age ● Lethal episode during sleep ● Death unexplained by CH	● Unexplained after review of the circumstances	● Unexplained after complete autopsy
Specific definition			
Category IA SIDS	1. Older than 21 days, under 9 months 2. Normal CH 3. Full-term pregnancy (≥ 37 weeks) 4. Normal growth and development 5. No similar deaths in siblings/relatives	● Scene investigation performed and gave no explanation ● Safe sleep environment ● No evidence for an accident	1. No lethal pathological findings 2. No unexplained trauma, abuse, neglect, or unintentional injury 3. No substantial thymic stress 4. Toxicology, microbiology, radiology, vitreous chemistry, and metabolic screening negative 1–4 and
Category IB SIDS	1–5 (criteria for category IA SIDS)	Scene investigation was not undertaken	5. One or more of the following analyses were not performed: toxicology, microbiology radiology, vitreous chemistry, and metabolic screening 1–5 and
Category II SIDS	Differences to category I criteria: 6. Age range (0 to 21 days, 270 to 365 days) 7. Neonatal/perinatal conditions that have resolved by the time of death 8. Similar deaths in siblings, near relatives	Mechanical asphyxia or suffocation by overlaying not determined with certainty	6. Abnormal growth and development not thought to have contributed to death 7. More marked inflammatory changes or abnormalities not sufficient to cause the death
USID	● Criteria for cat. I or II SIDS are not fulfilled	● Alternative diagnoses of natural or unnatural death are equivocal	● Autopsy has not been performed

USID – Unclassified Sudden Infant Death; CH – Clinical history.

4. Informing parents on the risk of further deaths (SIDS) in the family
5. Amending the death certificate

It is recommended that a standardized protocol should be used for all postmortem investigations. In 2007, an international and interdisciplinary group published such an extended protocol in Forensic Science International. This protocol includes a recommendation for additional investigations as well as a detailed sampling scheme.

Typical Macroscopic Findings

In SIDS cases, unspecific but typical findings can be seen. Most of the infants are properly developed in accordance with their age and well nourished. In about 35% of cases, signs of sweating have been determined before death: the hair, clothing, and sometimes the bedclothes are found to be wet. Lips and nail beds are cyanotic. Livores are often found on the front side because of the frequent use of the prone sleeping position. Livores are absent around the mouth and nose in cases of a face-down position, which may be indicative of the occlusion of both.

In about 40–60% of victims, a white, sometimes hemorrhagic foam is localized in and sometimes around the mouth, indicating the development of lung edemas. In more than 90% of all victims, petechial hemorrhages are found subpleurally, subepicardially, and in the thymus.

- Generally normally developed infants
- Heavy sweating before death (around 35% of all cases)
- Signs of vomiting and terminal aspiration of stomach contents ([Figure 2](#))
- Cyanosis of nail beds and lips
- Often typical livores at the front (due to prone sleeping position)
- Bloody foam in front of nose and mouth
- Often a hemorrhagic lung edema
- Dystelestatic lungs
- Subpleural and subepicardial petechia ([Figure 3](#))
- Petechia in the thymus ([Figure 4](#))
- Empty bladder
- Mild brain edema

Histological Changes

A histological investigation is mandatory in pediatric pathology. Histology is necessary to describe the quantity and quality of preexisting diseases, hypoxic changes, and other findings indicating unnatural causes of death. It is therefore necessary to take samples of all organs and tissues during autopsy. If possible, the central nervous system should be investigated by a neuropathologist experienced in infant death. Findings like mild edema, congestion, and some foci of gliosis are common in SIDS. Meningoencephalitis, aplasia, or severe dysplasia of important nuclei or signs of acute or repeated hypoxemia also have to be considered as causes of death.

Table 3 Risk factors for SIDS

Modifiable risk factors	OR (95% CI)
Prone sleeping position	6.08 (3.33–11.08)
Side sleeping position	2.01 (1.38–2.93)
Smoking of the mother in pregnancy	3.43 (1.39–8.46)
Smoking in the presence of the baby	3.41 (1.98–5.88)
Soft sleeping surface	3.0 (1.1–8.7)
Quilts, duvets, and sheepskin in the baby bed	2.20 (1.21–4.00)
Bed sharing in the parental bed	2.73 (1.34–5.55)
Sofa sharing	21.77 (3.79–125.00)
Overheating (hot room temperature and/or many layers of clothing and/or thick duvet)	3.52 (1.74–7.11)
Other risk factors	
Young mother (<20 years)	18.71 (6.00–58.32)
Low socioeconomic status	3.00 (1.35–6.69)
Protective factors	
Breast feeding	0.48 (0.28–0.82)
Use of pacifier	0.39 (0.25–0.59)
Timely immunizations	0.54 (0.39–0.76)

Odds ratios and 95% confidence intervals from the CESDI study and the German GeSID study.

**Figure 2** Aspiration of stomach contents (milk) in large bronchi.

In the lungs, hemorrhagic alveolar edema, dysteleatic regions, congestion, and bronchus-associated lymphatic tissue in the lung periphery are common findings in SIDS, as are intra-alveolar macrophages. Mild respiratory tract infections – often caused by various types of viruses – can be observed in up to 60% of cases, but these are usually not sufficient to explain

**Figure 3** Petechial hemorrhages subepicardial.**Figure 4** Hemorrhages in thymus.

the death. Only in cases showing severe infection (interstitial pneumonia showing bacterial superinfection, bronchopneumonia, and severe bronchiolitis) with septicaemia/viraemia, it is possible to consider infection as a cause of death.

In a small number of cases, histological investigations of the myocardium show findings typical for myocarditis, structural anomalies, or disturbances of the cardiac conductive system. In case of inflammation, immunohistochemistry can assist in characterizing the cell types involved.

The histological investigation of the intestine can show malformations (congenital aganglionic megacolon), infections, and other disturbances, which sometimes cannot be diagnosed macroscopically. Gastroenteritis can be of relevance to the cause of death if the disease is accompanied by significant dehydration or if it is caused by bacteria, which are able to excrete toxins.

The investigation of lymphatic tissue is helpful in diagnosing stress before death and in detecting a systemic reaction as a symptom of local inflammation. Until now, it has not been possible to show pathological immunoreactions as a cause of SIDS.

Postmortem Investigation

According to the SIDS definition, the circumstances of death and the place of event should be investigated by an experienced

Table 4 Death scene investigation

<i>External conditions</i>	<i>Surrounding</i>	<i>Situation found dead</i>	<i>External examination of the corpse</i>
Size of room	Type of bed	Body position	Signs of death
Size of Windows	Type of blanket	Clothing	Time of death
Heating	Size and weight of blanket	Covering	Resuscitation
Air exchange rate	Type of mattress	Sweating	Signs of Violence
Room temperature	Toys in bed	Vomiting	Body temperature
Temperature outside		Fixation used	

medical specialist, forensic scientist, pediatric pathologist, or pediatrician in collaboration with the police. In some countries, this is carried out by forensic nurses. The autopsy should be performed as early as possible to avoid significant postmortal changes of the body. The autopsy may also need to incorporate additional investigations regarding histology, toxicology, bacteriology, virology, neuropathology, and clinical chemistry. Finally, the infant's development should be analyzed, taking into account all the medical documents that are available.

Death Scene

This investigation should be performed as early as possible. In some cases, the death scene investigation can give important hints to explaining the situation leading to death as well as the cause of death (rebreathing of CO₂ or hyperthermia). Furthermore, the investigator has the opportunity to ask the parents directly for details of the clinical history before autopsy. The investigation includes an initial external examination of the body, the measurement of the body temperature, an investigation of the room conditions (size, temperature, heating system, air exchange rate, and bed covering), and of the sleeping environment, and necessitates equipment (thermometer, scales, and camera, [Table 4](#)).

Autopsy

An autopsy is a mandatory part of any investigation into sudden and unexpected infant deaths as the external investigation alone is not sufficient for rendering diagnosis with regard to the cause and manner of death. The autopsy should be done by a pathologist with experience in pediatric and forensic pathology. Some standardized autopsy protocols (Sheffield Protocol, Nord SIDS Protocol, International standardized autopsy protocol) have been developed and published. Before autopsy, an X-ray investigation should be done to detect fresh and old fractures and bone anomalies. Then, material can be taken for microbiology (swabs from the mouth and nose, and fluid from the spinal canal). The next stage involves an external examination of the corpse, followed by an internal investigation, including all body cavities. Body fluids and specimens for microbiology and virology should be taken using sterile instruments. The most common findings are *Staphylococcus aureus* in the nose and CMV or RSV in lungs. Further material has to be taken for toxicological and histological investigations. Different staining methods are useful to investigate the tissue specimens ([Table 5](#)).

Table 5 Routine staining methods for tissue specimens

<i>Staining method</i>	<i>Tissue</i>
Hematoxylin–eosin	All specimens
Fat	Myocardium, liver, muscle
Alcianblue-PAS	Lungs
Berlin blue	Lungs, spleen
PAS	Kidney
Giemsa	Ribs
Van Gieson	Brain

Clinical History

An analysis of the pregnancy (complications), delivery (position of infant, duration, complications, APGAR score, percentile), the infants' development (height and weight, previous diseases, hospital treatment, food, vaccination state), and the situation immediately before death (signs of infection, crying, feeding problems) is recommended. To evaluate autopsy findings, it is important to know if resuscitation attempts were done and by whom (parents and/or emergency doctor).

Cause of Death

In accordance with the investigation described, approximately 3–6% of cases can be classified as unnatural deaths. Up to 25–30% can be diagnosed as natural deaths due to defined causes ([Table 1](#)). The remaining 60% plus can be attributed to SIDS. The diagnosis is made by exclusion. Of these, a small percentage can be diagnosed as SIDS Ia (San Diego definition), whereas the majority displays minor pathological changes compatible with the diagnosis of SIDS Ib or SIDS II.

Hypotheses of Possible Causes of SIDS

A number of theories on possible causes of SIDS have been proposed in the past, but only a few have been clearly proven, mostly in individual cases. The earliest recorded death is that of an infant reported in the Old Testament, which was attributed to suffocation caused by overlaying (I Kings, 3:19). In 1830 Paltauf, supposed that such death could be due to suffocation by an enlarged thymus gland, which compressed the trachea (Status thymolymphaticus). After the Second World War, suffocation by a soft blanket on the mouth and

nose was the favored theory. About 40 years ago, Naeye published his observations of SIDS cases, suggesting that seven different findings could be suitable as tissue markers indicating hypoxia. By measuring the biochemical marker of acute hypoxia, hypoxanthine in vitreous humor, Rognum et al. showed in 1988 that a large proportion of SIDS victims had had significant periods of hypoxia before death. In 1972, Steinschneider introduced his sleep apnea theory, which became the theoretical basis for the monitoring of infants showing 'atypical' breathing patterns. He investigated five infants who showed prolonged periods of apnea during sleep. However, it was later found that two of these infants had died due to homicide. In parallel, it was discussed whether or not infections could influence or trigger the sudden death. Blackwell et al. hypothesized that an overwhelmingly proinflammatory response to bacterial toxins (as an inflammatory response to sepsis) may cause physiological changes leading to death. In the late 1980s and 1990s, SIDS research became more and more interdisciplinary, and typical risk factors for SIDS were identified by a number of epidemiological studies in different countries and regions. In the second half of the 1990s, molecular genetic studies were performed to investigate the genetic basis of functional disturbances. Possible cardiovascular causes of SIDS, for example, include abnormalities of the cardiac conduction system. In addition, ventricular tachycardia or fibrillation, often found without evidence of structural heart disease (so-called primary electrical disorders), may be associated with sudden cardiac death in neonates. One such disorder is long-QT syndrome (LQTS), which is characterized by increased sensitivity of the myocardium, with an increased propensity to developing ventricular fibrillation. Several studies have investigated a potential association of prolonged QT interval and SIDS and found that 1–10% of SIDS victims showed mutations in genes associated with LQTS. Other study groups investigated the serotonin transporter gene because of a reported decreased serotonergic receptor binding in brainstems of SIDS victims, but with inconcordant results. Further studies focused on genes that are involved in the early embryology of the autonomic nervous system (ANS), genes of nicotine metabolism, and genes regulating inflammation, energy production, hypoglycaemia, other metabolic disturbances, and thermal regulation. Rognum investigated the significance of mtDNA changes, complement component C4 polymorphisms, and polymorphisms of the interleukin 10 gene. Schneider first demonstrated the link between signs of infection before death in SIDS and partial deletions of the C4 gene.

Nevertheless, the main result of these studies is that SIDS victims show different gene variants for some of the investigated genes compared to controls. However, only in a small percentage of SIDS cases can the death be explained by such changes.

As early as 1972, Wedgewood introduced a 'three hit model' for SIDS suggesting that sudden and unexpected death may occur if three conditions are fulfilled simultaneously:

1. An infant is at a vulnerable developmental stage.
2. A predisposing endogenous factor(s) is present.
3. An exogenous trigger initiates the lethal process.

This hypothesis was later taken up and modified by Rognum and Saugstad, Filiano and Kinney, and Kahn. In particular, Rognum et al. included 'genetic risk factors' or 'genetic make up' as predisposing factors. The main advantages of these 'three hit theories' (in contrast to others) are that most of the information from pathology, neuropathology, microbiology, physiology, epidemiology, and pediatrics can be included in one of the three main areas, and that these models enable integration of new knowledge.

Currently it is very difficult to maintain an overview of the multiple investigations being conducted in the various fields of SIDS research, that is, a search of PubMed for the term 'SIDS' finds nearly 10 000 publications – including 1300 from the years 2005 to 2010. The results reported are sometimes not directly comparable as some authors have used their own definitions for cases and controls, and the diagnosis of SIDS has not always been confirmed by autopsy and additional investigations, and is therefore not in accordance with standard definitions.

Glossary

Bullet embolism Weak bullets or pellets may enter a blood vessel on one side without being able to perforate the opposite side so that they remain inside the vessel where they are transported along arteries or veins until they lodge in a more distal part of the systemic or pulmonary circulation (in body parts away from the wound channel).

Kinetic energy The kinetic energy of a moving object is equal to the mass multiplied by the square of the speed,

multiplied by the constant $1/2$. In SI units, the kinetic energy is measured in joules.

Simulant In the context of wound ballistics, simulants are materials that react to bullets in a manner similar to homogenous tissue as regards density, elasticity, capacity to absorb energy, etc. Therefore, they are suited for reproducible wound ballistic experiments. The most common simulants of soft tissues are gelatine and glycerine soap.

Introduction

Firearm injuries are regarded as a special form of blunt trauma. The damage to the organism is caused by the impact of a single projectile (or a multitude of pellets) propelled from a barrel by high-pressure combustion gases and striking the body at a high velocity. Gunshot wounds, in a broader sense, are also lesions caused by blank-cartridge weapons as well as injuries due to livestock stunners, stud guns used in the construction industry, and similar devices.

Wound Ballistics

Exterior ballistics deals with the behavior of the projectile after leaving the barrel (trajectory, velocity, etc.), while terminal ballistics covers the interaction between the projectile and the target. If the target is a human or animal body, one speaks of wound ballistics.

Fundamentals of the Wounding Capacity

The wounding capacity of a projectile is partly due to the direct destruction of anatomical structures along the bullet track by crushing, punching, and tearing. Another type of lesion is caused by changes in the pressure and displacement of tissue (with stretching and shearing) around the permanent wound channel. The extent of mechanical damage depends on the amount of kinetic energy (E_k) released in the tissue.

When a projectile penetrates the tissue, it is displaced laterally (radially) – that is, at right angles to the bullet path – thus forming a temporary wound cavity, whose diameter can be considerably larger than the bullet. The radially displaced tissue then moves back in the opposite direction toward the geometric bullet path.

The process just described is especially marked with high-energy projectiles, such as those fired from military and

hunting rifles. In fluid-filled organs (e.g., heart, urinary bladder) or in the skull, the radial expansion may lead to a hydrodynamic effect with bursting of the encasing structures. Cases in which the brain is completely flung out of the cranial cavity are referred to as exenteration shots. Even a shot with a smaller transfer of E_k may cause indirect lesions away from the wound track, for example, skull fractures, cerebral contusions, and stretch mark-like tears of the facial skin.

The ‘permanent’ wound channel represents the destructive passage of the bullet itself. The path is filled with blood and is surrounded by a more or less wide zone in which the tissue was temporarily stretched, thus suffering structural damage (‘zone of extravasation’).

By firing test shots at ‘simulants’ such as gelatin or glycerin soap, the transfer of E_k in biological soft tissue can be visualized, as the density of these materials is similar to that of muscle. In contrast to elastic gelatin, soap shows an almost plastic deformation. The bullet path and the volume of the cavitation remaining after the firing of the shot are proportionate to the energy transferred.

A stable bullet with a low deformation potential (full-jacketed projectile, as used in military ammunition) produces a ‘narrow channel’ in the simulant at first, which then opens into the larger temporary cavity as the projectile moves in a sideways position (when tumbling) and imparts more energy to the surrounding tissue. An expanding deformation of the projectile also increases the effect of the radial displacement and thus the volume of cavitation. In deformation projectiles (e.g., semi-jacketed hollow-point bullets as used in civilian hunting ammunition), the cavity starts forming immediately after penetration. A fragmentation of the projectile results in a multitude of wound tracks.

When projectiles of identical design, head configuration, and mass are fired, the transfer of energy in a dense medium and thus the extent of the temporary cavity essentially depend on the velocity of the bullet.

Figure 1 Forty-three-year-old homicide victim killed by three gunshots. The shots were fired from a 7.65 mm caliber pistol. Each of the bullets entered more than one body part (reentry shots). The full-jacketed bullets recovered at autopsy are shown in the right upper corner.

Wound Track

In gunshot injuries, the bullet may remain lodged in the body, or perforate it completely (through-and-through shot), or hit only the surface tangentially (graze wounds). In the first-mentioned type of gunshot wound, there is an entrance, but no exit wound. Rather often, projectiles traveling at a low velocity remain lodged under the tough and resilient skin on the side of the body opposite to the entrance wound, where their final position can be recognized by a hematoma and/or a palpable resistance. A radiological examination is advisable in any case to determine and document the localization of bullets and bullet fragments retained in the body.

For the determination of the angle of fire (in relation to the horizontal, sagittal, and frontal planes of the body), it is imperative that the length of the wound track and the localization of the entry and exit wounds or, in shots with the projectile retained inside the body, the final position (height from the plantar plane and the lateral distance from the median plane) of the bullet are exactly measured and recorded.

In most cases, the wound track in the body is linear. A full-jacketed rifle bullet, however, may produce a curved bullet path if its length in the body is longer than 20–30 cm. The deviation from the straight line begins when the projectile first moves into a lateral position, that is, in the region of the first cavitation, as the pressure gradient along the projectile becomes asymmetrical, thus creating a force component lateral to the direction of the movement.

Nonlinear bullet paths are often caused by internal ricochet. Inside the cranial cavity, such ricochets are seen in 10–25% of the cases and occur if the projectile is deflected from the internal table of the skull with a low residual energy. Bullets either ricochet back into the brain at an acute angle or pass along the inner surface of the skull producing a curved wound track in the underlying brain.

The latter type of ricochet occurs not only on the concave side of the cranium but also on other inner surfaces (e.g., ribs) if a concave boundary surface continuously changes the direction of the bullet.

In a perforating shot, the projectile produces an exit wound as it leaves the body. Bullets with a low residual energy are

sometimes no longer capable of perforating the clothing covering the exit wound. After having passed through one part of the body (e.g., the upper arm), the bullet may reenter another part (e.g., the thorax; **Figure 1**).

Graze shots produce groove-like lesions on the body surface, occasionally accompanied by short tears along the wound edges. If a projectile strikes the body with low residual energy, but does not penetrate, the affected skin may show an excoriation and/or a hematoma.

Intermediate Targets, Deflection of the Projectile

For the interpretation of a gunshot wound, it may be essential to know if the projectile struck the human body primarily or if it interacted with an intermediate object. For example, if the bullet first passes through an intermediate target, such as a door, the typical 'ring of dirt' on the site where it entered the clothing or the body is missing, because the grayish-black depositions adhering to the bullet surface were already wiped off at the primary target.

When a bullet passes through the dense medium of an intermediate target, it loses its gyroscopic stability, resulting in a rotation around a lateral axis. If such a bullet then hits the body in an oblique or sideways position, the entrance wound is elongated and there is a higher loss of energy in the initial section of the wound track. Analogous effects may be seen when the bullet was already deformed at the primary target.

If a projectile is deflected by an intermediary target instead of penetrating it, one speaks of a ricochet. A change of direction may happen, for example, if the bullet strikes stone, concrete, or asphalt. In such cases, the bullet often shows a flattened, mirror-like surface. The deformation and/or fragmentation of the ricochet bullet may cause an atypical entrance wound with no, or an incomplete ring of dirt. Owing to the loss of velocity and the instability of the ricocheting projectile, its depth of penetration is less than in primary hits after an undisturbed trajectory.

Lethal Gunshot Injuries

According to statistical investigations, about 20% of gunshot injuries are primarily lethal, that is, the victims die before receiving medical care.

Generally, fatal consequences of a gunshot wound have also to be expected if weapons are used, which lay people would not consider very dangerous (e.g., air guns, blank-cartridge weapons, and 0.22 caliber rimfire rifles). For example, bullets fired from conventional air guns (with a common barrel diameter of 0.22 or 0.177 in, that is, 5.6 and 4.5 mm, respectively) may perforate the thin temporal squama or penetrate into the cranium via the orbital cavity. The gas jet of blank-cartridge guns has repeatedly caused penetrating skin lesions, bone fractures and lethal injuries of vessels or organs, when fired from a very short distance. Of course, projectiles with a low energy fired from 0.22 caliber rimfire weapons may also produce fatal injuries if major organs or great vessels are hit along the bullet track.

In gunshot injuries with a fatal outcome, the direct lethal effect may be due to various causes. A special case is the gunshot-related 'exenteration' of the brain from the skull. When the shot strikes the nape of the neck or the occipital region,

it may directly destroy vital centers of the brain stem. More often, it is not the cerebral lesion as such, but the subsequent increase in the intracranial pressure (due to intracerebral, subarachnoidal, and subdural bleeding, sometimes associated with cerebral edema) that is responsible for the lethal outcome.

Gunshot fractures of the bony skull base are often followed by a hemorrhage into the nasopharynx; if the victim is unconscious, fatal aspiration of blood will result. Gunshot-related lacerations of the venous sinuses may act as entrance sites for air bubbles, possibly leading to death from venous air embolism.

Injuries to the heart, great vessels, or parenchymatous organs cause massive internal bleeding with consecutive hemorrhagic shock. Gunshots to the lung with traumatic pneumothorax are an acute threat because of the impaired respiration — especially if both sides are involved. Inflammatory complications are potential causes of delayed death.

Ability to Act

It is often wrongly believed that a gunshot to the head or the trunk always incapacitates the victim immediately. This opinion is disproved by a multitude of well-documented cases in which gunshot victims performed surprisingly differentiated actions even after severe traumatization of vital organs.

If a victim becomes unable to act, this is usually due to functional impairment of the central nervous system caused either directly by tissue lesions or indirectly by insufficient oxygen supply. Immediate incapacitation is to be expected if the bullet destroyed parts of the brain essential for physical activity — with exenteration of the entire organ in extreme cases. Targets of immediate incapacitation are the upper cervical spinal cord, the brain stem, the cerebellum, the basal ganglia, the motor areas of the cerebral cortex, and the large motor nerve tracts. The bullet need not necessarily pass through these cerebral regions directly, as the gunshot-related pressure and shearing forces can also damage nerve structures and impair functions away from the bullet path.

Cerebral hypoxia with consecutive unconsciousness following gunshots to the chest is mostly due to massive loss of blood. However, even if the bullet strikes the heart, the aorta, or other large arteries, blood circulation will hardly cease immediately and even then the oxygen reserves left in the brain may be sufficient for simple and short actions. Consequently, rapid, but not immediate, incapacitation is to be expected after gunshot injuries of the heart, the aorta, and the pulmonary artery. On the other hand, victims will go down immediately if struck in the spinal cord.

The pathophysiological considerations just described have significant implications for the assessment of suicides in which several shots were fired. Continued ability to act after a cerebral gunshot injury is observed especially if low-energy ammunition was used and/or the bullet track did not involve the above-mentioned structures of immediate incapacitation (upper cerebral spinal cord, brain stem, motor cortex areas, and large motor pathways). In most suicides with more than one shot to the head, only the frontal lobe(s) or one of the temporal lobes of the brain is involved. Multiple gunshots to the cardiac region are seen more often than multiple suicidal shots to the cerebral cranium.

Stopping Power

The term ‘stopping power’ is used to characterize the potential biological effect of a projectile, in particular, its capacity to prevent a person from moving or attacking. Actually, the idea conveyed by movies and TV films that the impact of a bullet stops or even knocks down the affected person is not true in real situations. Bullets do not have the potential to throw people off their feet. Otherwise, the person who shoots the gun would be knocked over, as action and reaction are equal and opposite.

In fact, the effectiveness of the projectile depends on the amount of energy transferred to the body, leading to local displacement and destruction of tissue. In this context, the shape of the bullet is essential for its effectiveness: If the bullet head is blunt, deceleration and energy transfer are larger. However, in real cases, the effect of a bullet not only results from its effectiveness but also to a large extent from the point of impact, that is, from the affected region and the relevant anatomical structures.

Embolism of Projectiles

The rarely seen transport of bullets or shot pellets within the vascular system is called embolization. Most of the embolized projectiles are of smaller caliber and low velocity, which is sufficient only to penetrate the artery or vein, but not to exit the vessel again, so that the foreign body, which is now localized inside the vessel, may be moved to a region of the body away from the bullet path, where it can be easily visualized by radiography.

Bullet and pellet embolization is mostly seen in the arterial system (entry via the heart or the aorta and transport, e.g., to the leg arteries). In rare cases, a projectile may enter a vein and travel from there to the (right) ventricle or to the branches of the pulmonary artery.

Delayed Effects

In survived gunshot injuries with retained bullets or pellets, the question arises as to whether this may cause chronic lead poisoning. Generally, the risk is assessed as being very low. Most cases reported in the literature refer to patients with projectiles lodged in the joints or bones. The latency period until an intoxication becomes manifest ranges from a few months to several decades.

Criminalistic Aspects

The purpose of clinical examination or autopsy of persons with gunshot injuries is to answer the following questions:

- Do the findings confirm the assumption of a gunshot injury?
- Number of hits?
- Did a striking projectile pass through the body or is it lodged in the body or did it produce a graze wound?
- What was the direction and angle of fire (trajectory)?
- Are there any clues as to the type of weapon and ammunition used?

- From what distance was the shot fired (contact shot, close-range shot, distant shot)?
- Do the wound characteristics in connection with the traces at the scene suggest self-infliction or involvement of another party?
- Did the gunshot injury result in immediate incapacitation?

Entrance and Exit Wounds

In order to determine the direction of fire, it is imperative that entrance and exit wounds are interpreted correctly.

Characteristics of Entrance Wounds

Typical features of an entrance wound in the skin are:

- punched-out hole (i.e., a central tissue substance defect that cannot be closed by approximation of its edges);
- marginal zone without epidermis (abrasion ring); and
- grayish-black ring of dirt (provided that the projectile did not pass through another target first).

When the shot was fired either with the muzzle in contact or at close/intermediate range, the respective signs can be regarded as further evidence of a bullet entry wound (**Figure 2(a)**).

Entrance Hole

The central entrance defect is roundish (if the projectile strikes at a right angle, **Figure 2(d)**) or oval (if it strikes at an oblique angle, **Figure 2(e)**). The diameter is usually smaller than that of the bullet.

The discrepancy between the caliber of the projectile and the diameter of the permanent entrance hole can be explained by the elastic behavior of the skin: On impact of the bullet head, the edges of the defect temporarily move centrifugally due to the radial forces causing a reversible widening of the bullet entrance hole. When the deformation forces cease, the elastic skin resumes its former shape so that the permanent entrance defect may be much smaller than the diameter of the bullet (this discrepancy is particularly marked on the palms of the hands and soles of the feet). The size of the skin wound, therefore, does not allow one to draw accurate conclusions as to the caliber of the projectile.

Figure 2 Bullet entrance sites (a) Entry wound caused by a 0.22 LR projectile in front of the right ear showing a central tissue defect with a black ring of dirt covering the underlying abrasion collar. On the surrounding skin a zone of faint soot soiling and stippling can be seen (close-range shot). (b) Bullet hole in the uppermost layer of the clothing with a pronounced bullet wipe-off. (c) Bullet entrance wound in the chest (originally covered by clothing) with a wide abrasion ring but without a ring of dirt (round nosed bullet, caliber 7.65 mm). (d) Entrance wound with punched-out skin defect and a remarkably narrow abrasion ring (9 × 19 mm police deployment cartridge QD PEP). (e) Angled shot (direction indicated by arrow).

The reason for the skin defect remaining at the entrance site is essentially that the projectile transports tissue particles into the depth of the wound track. Moreover, at the moment of impact, small skin particles are flung back against the direction of fire.

Abrasion Collar (Abrasion Ring/Margin/Rim)

The central entrance hole is usually surrounded by a circumferential loss of epidermis (and its natural pigmentation), forming a moist, reddish margin when fresh and later assuming a brownish color due to the drying of the unprotected corium (Figure 2(c) and 2(e)).

With the help of high-speed photography, Sellier was able to prove already in 1967 that the epidermis-free margin of the entrance wound is not caused by any major indenting with consecutive overstretching and local friction. When the bullet head strikes the skin, backscatter of marginal tissue particles is induced by the pressure exerted on the entrance site. The former idea that the bullet head indents the skin before penetration, thus causing marginal abrasion, is not correct. It also does not result from the bullet being hot nor from its rotating movement.

In the peripheral parts of the abrasion collar, the epidermis is often torn and detached like wallpaper, so that parching can progress beyond the epidermis-free zone after prolonged exposure to air. When the bullet strikes at an oblique angle, the abrasion ring is elliptic and eccentric, being wider on the side from which the shot was fired. A unilateral widening of the abrasion collar thus gives an indication of the direction in which the bullet was traveling.

If the skin of the entrance region is under water, no abrasion ring is formed. The same is true for shots to the palms and soles. Entrance wounds from high-velocity centerfire rifles may lack a typical abrasion collar but show small splits radiating from the edges (the so-called microtears).

Bullet Wipe-Off ('Ring of Dirt,' 'Grease Ring')

The criminalistic importance of the bullet wipe is due to the fact that – at least on the primary target – this finding is a reliable sign of a bullet entrance.

The term bullet wipe refers to the mechanism of formation: when the projectile hits a skin region not covered by clothing, sooty remnants and other residues deposited on the bullet's head are transferred to the wound margin, so that a grayish-blackish ring (partly) overlies the abrasion collar (Figure 2(a)). More often, this ring of dirt is seen on the uppermost textile layer (Figure 2(b)), but not (or only vaguely) on the margin of the entrance wound. In oblique gunshots, the bullet wipe is eccentrically enlarged on the side from which the shot was fired. The bullet wipe is not a sign of a close-range or a contact shot, as it also occurs in distant shots.

Exit Wounds

The exit wound presents as a slit-like or stellate severance of tissue (Figure 3). In typical cases, there is – in contrast to the entry wound – no real hole, that is, no tissue defect. This means that the wound usually can be closed by bringing the edges into apposition. An exit wound produced by a bullet passing sideways through the skin may be slit-like and, therefore, mistaken for a stab wound.

Often, though not always, the size of the exit wound is larger than that of the entry wound. In practice, the uncritical application of this unreliable 'rule' often leads to misinterpretations. Thus, contact shots fired to the head may show stellate entrance wounds with long radial tears; in such cases, the exit wound may be much smaller (Figure 4). In cases of splinter injuries (e.g., by fragments of explosive weapons), the entry wound is always larger than the corresponding exit. The

Figure 3 Exit wounds (a) Skin severance without any excoriation of the margins that could be brought into apposition (9 × 19 mm caliber pistol). (b) Stellate exit wound of the cheek (caliber .30-06 hunting rifle). (c) Shared exit wound on the back (9 × 19 mm caliber pistol). At the moment of discharge, the exit region was in contact with the ground.

Figure 4 (a) Suicidal contact shot to the right temple with a caliber 9×19 mm pistol. The entrance wound shows a central defect and radial lacerations of different length. (b) Irregularly shaped exit wound close to the left ear. The maximum diameter of the exit wound is smaller than the larger splits at the entry site.

differentiation between entrance and exit should never be made on the basis of simply comparing the wound dimensions.

The size of the exit wound mainly depends on the diameter of the temporary cavity at the site where the bullet leaves the body. In some cases, bone splinters carried along may also contribute to a larger exit hole. Many projectiles leave the body deformed and/or tumbling, which may also influence the shape of the exit wound.

It goes without saying that exit wounds cannot have a bullet wipe. Occasionally, the margins of the exit wound are abraded (shored) when a firm object (e.g., tight-fitting clothes, floor, wall, or back of a chair) is pressed against the body at the site of the exiting projectile (Figure 3(c)). Under such circumstances, the skin around the exit is abraded by the supporting surface. In contrast to the 'original' abrasion ring around the entry wound, in 'shored' or 'supported' exits, the area of abrasion is not concentric, but irregular or lopsided and often disproportionately large.

Classification of Entrance Wounds in Relation to the Range from Muzzle to Target

To understand the different features of gunshot entry wounds, it is necessary to be familiar with the major processes occurring when a firearm is discharged. As the trigger is pulled, the firing pin is released and strikes the primer in the base of the cartridge case. The detonating primer ignites the propellant. The subsequent burning (deflagration) of the gunpowder generates a large amount of expanding gas, which is under high pressure and propels the projectile down the barrel. The gas is composed of carbon monoxide, carbon dioxide, oxides of nitrogen, and other compounds. A small percentage of the powder grains remains unburned or only partly burned.

Already before the projectile leaves the barrel, a cloud of gunsmoke exits the muzzle. The term gunsmoke refers to the grayish-black combustion products of the powder that has not fully converted to gases. Essentially, gunsmoke consists of carbon in the form of soot.

Apart from the combustion gases and the finely dispersed soot, there are always unburned and partly burned powder grains expelled along with the projectile. The cloud of powder soot rapidly decelerates so that smoke soiling is to be expected only relatively close to the muzzle. The larger powder grains (having a diameter of at least several tenths of a millimeter) can also reach more distant targets.

The diameter of the spread and the density of soot and/or powder particles on a target are not only dependent on the range of fire but also on the cartridge type and the weapon (length of the barrel). Consequently, the range of discharge can only be evaluated by firing test shots with the respective weapon and ammunition.

In handguns, macroscopically visible traces of gunsmoke are to be expected up to a range of several centimeters. Depending on the weapon and ammunition, gunpowder grains may reach targets several decimeters away (in rifles also more than 1 m). The use of silencers strongly reduces the deposition of soot and powder particles, thus creating the false impression of a larger range of fire.

When a gun is discharged, two different light phenomena can be observed: first, the flame – a short, mostly dark red jet of fire caused by the not yet completely finished combustion of the powder particles; second, the muzzle flash – a glaring fire ball some distance away from the barrel end caused by the reaction of the incompletely oxidized combustion gases with the oxygen in the air.

With nitro powder, the extremely short impact of the muzzle flame is usually not sufficient to cause substantial burns on

the clothing or skin. Sometimes, frizzing may be seen on the hair near the entry wound. Thermal damage is possible in shots with nitro ammunition fired from a very short distance (near contact), if textiles made of thermolabile synthetic fibers melt on the underlying skin. If black powder ammunition is used, close-range shots may cause impressively large burns.

In forensic medicine, three ranges of fire are distinguished according to morphological criteria:

- contact range
- short/close and medium/intermediate range
- long/distant range

Contact Shots

The term 'contact shot' means that the muzzle was held against the body surface at the time of discharge. In contact shots, soot-containing combustion gases are propelled into the depth of the entry wound. They expand beneath the skin and blacken the initial section of the wound track (pocket-like

undermining, 'powder cavity' containing soot and gunpowder particles). As the combustion gases have a high content of carbon monoxide (up to 50%), the surrounding tissue often assumes a bright cherry-red color (cf. [Figure 7\(b\)](#)). In tight (hard) contact shots, nearly all the combustion products enter the wound ([Figure 5](#)), whereas in loose, angled, or incomplete contacts, some soot may escape between the muzzle and skin so that the adjacent surface is blackened ([Figures 6 and 7](#)).

The entrance region is bloated by the intruding powder gases and balloons backward against the muzzle end of the weapon, which is imprinted on the skin causing a 'muzzle abrasion' ('barrel marking,' 'muzzle contusion'). Mechanically, the muzzle imprint is mostly a patterned pressure abrasion with a tendency toward parching after exposure to air or – less frequently – an intradermal bruise ([Figure 5\(a\)](#)). Apart from the barrel end (or its contours), other constructional parts situated near the muzzle, such as the front sight and/or the recoil spring guide may also be imprinted.

Figure 5 Hard-contact gunshot wound to the right temple (caliber 9 × 19 mm pistol). (a) Imprint mark mirroring the muzzle end of the weapon. (b) Entrance hole in the underlying skull surrounded by intense blackening from powder soot. (c) Inner surface of the skull showing a cone-shaped widening of the hole. (d) Final position of the flattened projectile (e) on the left side of the skull cap.

Figure 6 Suicide by a loose-contact shot to the submental region (caliber 9×19 mm pistol). (a) The entrance hole is surrounded by a concentric zone of intense powder soot blackening. (b) Exit site in the parietal region showing 'outward beveling' of the bone defect and radial fractures extending from the gunshot hole. (c) Close-up view of the exit in bone.

Figure 7 Angled contact shot to the right temple, 0.22 caliber rimfire rifle, suicide. (a) Entrance wound with eccentric soot blackening of the margins. (b) Entrance hole in skull surrounded by faint soot staining. The muscle tissue adhering to the bone has a cherry-red color due to the formation of carboxyhemoglobin and -myoglobin. (c) Left side of the cranial vault after removal of the skull-cap; the mushroomed lead bullet (d) was lodged between dura and bone.

The muzzle contusion allows one to draw significant conclusions:

- The weapon was in contact with the skin at the instant of discharge.
- The configuration of the imprint mark corresponds with the constructional elements being in line with the muzzle or just behind. Therefore, the imprint mark can characterize the type of weapon used (e.g., revolver or pistol) or even a specific make or model.
- The imprint configuration may provide information as to the way in which the weapon was held at the moment of discharge. For example, an imprint of the front sight below the bullet entrance means that the weapon had been held upside down (i.e., with the handle pointing upward).

If the entrance wound is above a bony support (e.g., in the frontal and temporal regions), the subcutaneous expansion of the penetrating combustion gases may cause radial skin tears due to overstretching, resulting in a stellate wound of entrance (cf. [Figure 4](#)). This additional sign of a contact shot is facultative: Shots fired with low-energy ammunition such as 0.22 LR or 6.35 mm do not necessarily cause stellate lacerations even at sites having a bony support. Away from the entrance wound, stretch mark-like tears of the facial skin may occur, especially in shots to the forehead and the submental region.

Close- and Intermediate-Range Shots

In close-/intermediate-range shots, GSR (gunshot residues: soot and/or powder particles) are deposited around the entry wound. Usually, a distinction is made between close-range shots and medium (intermediate)-range shots.

Close-range shots are defined by the presence of a zone of powder soot soiling surrounding the bullet entrance (often associated with additional powder tattooing; [Figures 2\(a\)](#) and [8](#)). The grayish-black soot leads to skin or textile discoloration of a cloudy structure, whose intensity decreases with growing firing distance. Shots fired at an oblique angle result in an asymmetrical soot pattern with unilateral extension on the side of the shooter or away from it (depending on the angle at which the shot was fired and the range of fire). Interfering objects, such as clothing or body parts (hand), may partially filter out the gunsmoke. Flash suppressors, which are often

Figure 8 Homicidal close-range shot with a black powder gun (caliber 0.44 muzzle loading percussion pistol) showing soot soiling, pronounced stippling and singeing of the eyebrows.

used in military rifles, have lateral smoke outlets, which may produce a flower-like pattern of soot with several radial petals corresponding to the number of slits. In revolvers, there is a gap between the cylinder and the barrel, which allows the combustion gases to emerge sideward. The soot and the powder grains escaping from the gap may produce a characteristic linear or L-shaped mark if the skin or a fabric is in close proximity at the time of discharge.

The term medium-range shot is used if no zone of powder soot blackening is discernible around the entry wound any more, but there are unburned or partially burned gunpowder grains deposited on, or forced into, the skin or clothing. The penetrating capacity of the powder grains depends on the propellant (flake or ball powder, grain size), the weapon, the range of fire, and the surface properties of the target. At short shooting distances, grains may be driven through thin textiles and cause stippling on the underlying skin.

On the skin, the powder particles cause either superficial epidermal lesions (with subsequent drying) or – if deposited beneath the epithelium – petechial dermal hemorrhages. According to some authors, the term tattooing should be used to describe forceful in-driving, whereas the term stippling means the mere presence of impact markings.

The distribution pattern of powder tattooing/stippling varies according to the angle of fire: only perpendicular shots produce a radially symmetrical picture; in most other cases, the affected skin area is elliptic in shape. The entry wound may be localized outside the tattooing if the powder grains were partly filtered out by clothing or other primary targets. Pseudo-tattoo marks can be due to the fragments of an intermediate target, such as the window of a car. In such cases, fragments of glass may produce irregular stippling lesions on the person seated behind the perforated window.

Distant-Range Shots

In forensic usage, the term distant shot means that the weapon was discharged from such a distance that no soot and no powder grains could reach the body surface (skin or clothing in covered body regions). The minimum range for this type of gunshot wounds varies not only depending on the weapon and ammunition but also on the sensibility of the investigation method used.

The special methods of determining the range of fire cannot be discussed here. For securing and adequately preserving any GSR that may be present on the clothing or in the vicinity of entry wounds, close cooperation with the responsible experts is necessary. In any case, the relevant findings should be documented by photographs and also by x-rays, whenever possible.

Shotgun Injuries

Shotguns are hunting or sporting weapons intended to be fired from the shoulder. They are either single- or double-barreled, the barrels in the latter ones being arranged either side by side or 'up and under.' A so-called pump gun has a pipe magazine under the barrel, which can take up several cartridges. Usual shotgun shells with birdshot or buckshot contain a multitude of pellets, which first travel together for a short distance and then separate more and more. The increasing dispersal of the shot improves the

hunter's chance of striking a moving target, such as a hare or a flying duck. The criminal use of shotguns on humans is common, and improvisations, such as sawn-off barrels, facilitate the handling and hiding of the weapon. Shortening the barrel results in an increased spread of the pellets in midrange and distant-range shotgun discharges. Shot pellets are made from lead, which is easily deformed when striking dense tissue (**Figure 9(d)**).

A shotgun contact wound is produced when the muzzle is placed tightly against the body surface. The entrance wound roughly corresponds to the gauge and is of circular shape in most body regions, but stellate over the bone (due to the expansion of the intruding gases with consecutive backward ballooning of the skin). Sometimes, there is a clear imprint abrasion mark, for example, from the front sight or – in double-barreled weapons – from the nonfiring muzzle. The wound edges may be blackened, but most of the soot enters the body and is deposited in the depth of the wound. The surrounding

muscle is often colored cherry-red due to carbon monoxide. An intraoral discharge or a contact wound to the head (forehead, temple, or under the jaw) leads to massive destruction of the skull (bursting of the head or shooting off of the face) and is occasionally associated with evisceration of the brain.

Even in cases with extreme splitting of the face and the scalp, careful approximation of the wound edges helps in finding the entrance site. Loose-contact discharge allows the escape of sooty combustion gases, staining the skin around the entrance hole. Intermediate-range shots are characterized by the presence of stippling/tattooing from unburned propellant (up to 1 m, depending on the type of powder). In close-distance discharges, additional smoke soiling is seen.

The injury pattern of shot ammunition is mainly influenced by the distance between the muzzle and the target: As the range increases, the initially circular entrance hole shows scalloping of the wound edge (nibbling or crenation); from a distance of

Figure 9 Homicide committed with a 16 G shotgun (diameter of the pellets 3.5 mm) from a distance of about 2 m. (a) The medial margin of the entrance wound is crenated whereas the lateral side is lacerated and surrounded by satellite holes from peripheral pellets and grazing pellet wounds. (b) Radiological documentation of the shot pattern. (c) Left ramus of the fragmented mandible with grayish lead debris from ricocheting pellets (d).

approximately 2 m, peripheral pellets produce satellite-like holes outside the central entry defect (Figure 9). Ranges of several meters are characterized by a sieve-like wound pattern. If shots are fired from short distances, wads or plastic cups may either penetrate the body together with the shot or cause excoriations of characteristic shape on the victim's skin ('wad abrasion').

Shotgun slugs are large, single lead projectiles destined for smooth-bore shotguns and also for those having a choke at the end of the barrel. The hitting accuracy of shotgun slugs is considerably lower than that of rifle projectiles; as a consequence, they should not be used for distances beyond 35–50 m in hunting. Some shotgun slugs are designed according to the arrow principle (heavy front part and light rear part).

Internal Findings

The gunshot lesions of the inner organs can be discussed only briefly here. Special mention should be made, however, of bullet holes in the flat bones of the skull (cf. Figures 5(b), 5(d), 6(b), 6(c), and 7(b)). On the entrance side, the bone defect in the outer table is sharp edged and its minimum diameter roughly corresponds to the caliber of the projectile, whereas the inner table is beveled out in a cone-like manner. This characteristic widening on the exit side allows one to determine the direction of fire even in an isolated bone. For gunshot exit holes of the skull, the opposite is true: The outer table shows a crater-like defect (outward beveling). Projectiles striking at an acute angle produce keyhole-shaped entrance defects in flat bones with partial cratering of the outer table at the side away from the shooter. So the manner in which the bone breaks may indicate the inclination of the bullet path. Beveling is not restricted to the skullcap, as it is also seen in other flat bones, such as the sternum, the pelvis, and the ribs.

In contact shots to the cerebral cranium (e.g., the frontal, temporal, parietal, and occipital regions), soot deposits are found not only under the skin, but also around the bone defect (cf. Figures 5(b) and 7(b)) and on the underside of the lifted-off periosteum, often even on the outer surface of the dura mater.

In many cases, radial fractures extend from gunshot holes of the skull (cf. Figures 5(b), 6(b), and 6(c)). According to Puppe's rule, a secondary fracture line will cease when it meets a pre-existing fracture line, which may help one to determine the sequence of shots.

In soft tissue, the wound track collapses and/or is filled with blood. Postmortem probing of the bullet path involves the risk of causing artifacts and should therefore be avoided. Parenchymatous organs, such as the liver, the kidneys, and the spleen, may show large stellate wounds at the sites of entry and exit.

Whole projectiles or bullet fragments removed from the body by surgical intervention or during autopsy must be preserved for further laboratory investigation, including ballistic comparison. A recovered projectile provides information regarding the caliber, twist direction, number and width of lands and grooves as well as of the individual characteristics imparted by the inner surface of the barrel.

Blank firing pistols and revolvers are detailed facsimiles of real handguns. The blank cartridges destined for these weapons contain gunpowder, but no projectile. If the muzzle is held in

close proximity to the body surface or even in contact with it, the gas jet from the blank gun is capable of penetrating the skin and causing potentially fatal injuries.

Forensic Examination and Documentation

In all firearm fatalities, careful documentation is of utmost importance. This includes taking photographs and close-up views of each wound using a scale. The clothing must be preserved, as the uppermost layer may exhibit the bullet wipe around entrance holes and depositions of soot and/or powder particles in close- and medium-range shots, respectively.

Whenever possible, x-rays should be taken before autopsy in two planes (anteroposterior as well as lateral views). They are not only useful for permanent and objective documentation but also helpful in exactly locating and characterizing all bullets and any metal fragments, including separated jackets. Radiographs are also a valuable tool to find projectiles lodged in body regions, which are hardly accessible during autopsy (e.g., within the vertebral column). In addition, x-rays provide evidence that a bullet might have been deflected or embolized.

All wounds have to be described exactly with regard to their location using fixed landmarks, such as the base of the heels, the midline, the height above the buttocks, and the distance from the top of the head. The documentation should also mention the size and shape of each wound, the features of the wound margins and their surroundings, the presence or absence of GSR such as soot or stippling on the clothing and/or skin, the total length of the wound tracks, and, of course, the injuries to the internal organs.

It is important to recover any bullets or major parts thereof from the body of the victim. Subsequent laboratory investigations may help in identifying the bullet type and assigning the fired bullet to a specific weapon.

Manner of Death

To classify a gunshot wound as suicidal, homicidal, or accidental, a synoptic evaluation of the scene and the circumstances of the case, the evidence obtained from the injuries, the victim's clothing, and the laboratory investigations concerning the weapon, ammunition, and the range of fire has to be made. Easy access to weapons due to permissive legislation is associated with increased rates of firearm homicide and suicide.

From the medicolegal point of view, the question has to be answered whether the entry wound is localized in a region typical for suicides: temple (cf. Figures 4, 5, and 7), mouth (Figure 10), cardiac region, forehead, and submental region (cf. Figure 6(a)). In almost all cases of suicide, the muzzle is held against the body or inserted into the oral cavity. In shots to the chest, the skin is seldom bared before. In more than 20% of the suicides committed with pistols or revolvers, the weapon is found clutched in the firing hand.

The examination of hands to detect GSR, especially lead, antimony, and barium originating from the primer, can be mentioned only briefly here. These residues escape mainly from the cylinder-barrel gap (in revolvers) or from the ejection port (in automatic pistols) and come to rest on the skin and/or

Figure 10 Intraoral shot from a 9 × 19 mm caliber pistol (suicide). (a) Symmetrical tears on the inner surface of the lower lip. (b) Dorsum of the tongue with soot deposition (near the apex) and tangential wound from the projectile (c).

Figure 11 (a) Left hand used by a suicide to steady the barrel of a pistol: soot depositions on the radial aspect of the index finger. (b) Ulnar aspect of the right hand which had fired a pistol. The skin is spattered with a spray of blood.

clothing, where they can be collected for subsequent chemical analysis. The presence of GSR is detected by flameless atomic absorption spectroscopy or by scanning electron microscope–energy dispersive x-ray spectrometry.

Sometimes, clues suggesting suicide are found even on examination with the naked eye (Figure 11), for example, spray of blood or tissue deposits on the firing hand ('back-spatter' from the entry wound), traces of soot on thumb and index finger (if the muzzle end was held against the entrance site with one hand), or injuries from the edges of the recoiling slide. Direct and prolonged contact of the skin with the steel parts of the weapon in a moist environment promotes the formation of brownish rust stains. This phenomenon is found especially in suicides, although it is no proof that the shot was self-inflicted.

Injuries Caused by Explosives

In peacetime, injuries and fatalities owing to the detonation of explosives (letter or parcel bombs) are seen mainly in connection with politically motivated or terrorist attacks against persons, vehicles, and buildings. Accidents are mostly due to natural gas ignitions, chemical explosions, or improper handling of explosives, fireworks, etc. In countries without terrorist activities, suicides by explosives are rare and usually restricted to persons with a pertinent professional experience (Figure 12).

The injury pattern is typically characterized by a complex combination of different lesions. Mechanical tissue destruction up to traumatic amputation and evisceration is caused by blunt force (exploding device and other objects impacting the body,

Figure 12 Occupation-related suicide of a blaster who had placed the explosive charge next to the back of his neck resulting in decapitation with concomitant soot soiling.

pressure wave), often associated with penetrating injuries from splinters, burning, and soot blackening of the skin. The internal examination may reveal organ and vascular damage, skeletal fractures, ruptured tympanic membranes, and acute pulmonary emphysema. A complete body x-ray examination should be performed whenever possible.

Glossary

Expert witness An expert witness is a person, who by virtue of education, training, skill, or experience is believed to have expertise and specialized knowledge in a particular field so that others (including authorities such as courts)

can rely upon the expert's opinion about an evidence or fact issue.

Fact witness A fact witness is a person with knowledge about what happened in a particular case, who testifies in the case about what happened by reciting facts and/or events.

Introduction

In the wider sense, clinical forensic medicine means the application of clinical knowledge and skills to living individuals corresponding to the special needs of the respective legal, judicial, and police systems. The organization of clinical forensic work differs considerably from place to place, partly depending on the legal situation (e.g., the so-called adversary system of criminal procedure in the Anglo-Saxon tradition on the one hand and the 'inquisitorial system' in Continental Europe on the other). It is therefore impossible to deal with any regional peculiarities, and this article is necessarily confined to a general view of the main fields of work usually done

by forensic medical examiners, sometimes also called 'forensic physicians,' 'forensic medical officers,' 'police surgeons,' or 'clinical forensic practitioners.' **Table 1** shows typical reasons for their attendance although the focal points of demand may vary to a large extent.

From the topics listed in **Table 1** it becomes obvious that clinical forensic medicine comprises a large spectrum of duties which are usually handled by doctors of several disciplines involving the medicolegal interface: legal medicine (as a 'stand-alone' subject in the undergraduate curriculum at medical schools of Continental Europe), forensic pathology, psychiatry, emergency medicine, pediatrics, gynecology, public health, and others.

Due to global migration, the need for forensic age estimation in living persons without valid identification documents has greatly increased. According to current recommendations issued by the *Study Group on Forensic Age Diagnostics*, age determination in living adolescents and young adults should be based on the results of a physical examination, an x-ray of the hand, and a dental examination.

Some aspects of clinical forensic medicine are dealt with in dedicated articles and will not be discussed here.

Clinical Examination of Living Victims

Victims of an alleged crime or suspected perpetrators often have to be examined with regard to the presence of injuries. The observations and the medical report on the wounds are likely to play an important part in any subsequent legal proceedings. Therefore, the physical examination and the documentation of the relevant results must be performed in an adequate and accurate manner. Descriptions and conclusions should be phrased in terms which are also intelligible to lay persons. If scientific language is inevitable, an explanation must be given.

Table 1 Categories of clinical forensic work

1. Examination of living victims:
 - a. Bodily injury due to criminal assault
 - b. Rape or other sexual crimes in adults
 - c. Physical and sexual child abuse
 - d. Spouse abuse and other kinds of domestic violence
 - e. Abuse of elderly persons
 - f. Torture
2. Examination of suspected perpetrators
3. Examination of self-inflicted injuries
4. Medical investigation in traffic accidents:
 - a. Examination of pedestrians
 - b. Determination of driver vs. passenger
5. Examination for fitness to drive:
 - a. Assessment of impairment to drive due to alcohol and/or drugs
 - b. Specimen taking (blood samples)
6. Assessment of the effect of drink and/or drugs on responsibility
7. Mental health assessment
8. Assessment of fitness to be detained and interrogated
9. Assessment of physical ability required for work
10. Reports, statements, expertise:
 - a. Written and photographic documentation of medical findings
 - b. Interpretation of wounds and other medical evidence
 - i. Conclusions as to the causation of injuries (e.g., which type of weapon has been used)
 - ii. Assessment of the severity of bodily harm and its dangerousness
 - iii. Identification of offensive and defensive injuries
 - iv. Medicolegal reconstruction of the circumstances and the course of events
11. Presentation of medical evidence in court:
 - a. Witness as to fact
 - b. Professional witness
 - c. Expert witness
12. Medical care of detainees:
 - a. Short-term custody (police)
 - b. Long-term custody (prison)
13. Health care of police officers
14. Determination of age

It is impossible to prescribe a standardized format to suit every case, as the circumstances differ so much. Apart from the actual examination procedures, it has to be decided if samples need to be taken (e.g., blood for alcohol or drugs, genital swabs, urine, hair samples, and so on). In most cases, photography is helpful and desirable, especially in complex and patterned injuries. Sometimes even the absence of visible injuries might be important, for example, in false allegations. For detailed recording of small marks such as tiny petechiae, a magnifying glass or an operation microscope is necessary. Whenever possible, the whole body from head to toe including the genitalia should be minutely inspected in a good light. In order to prevent any reproaches, it is recommended that a chaperone should be present whenever a male physician investigates a female patient.

Each medical report should contain some basic information on the victim, that is, size, stature, body weight, etc. All remarkable findings must be recorded and their location defined in relation to easily identifiable marks or fixed body parts (e.g., the middle line and the distance from the sole in upright position). The size and shape of each wound should be detailed by precise measurement using a ruler or a tape measure. If there are a multitude of wounds, it might be advantageous to group them according to their kind and severity or to their location within anatomical regions. Body diagrams or sketches can be helpful.

The margins of each wound require close inspection and accurate description: whether they are lacerated or incised, whether they are shelved or excoriated, whether there is bridging or embedment of foreign material (e.g., soil, glass, paint). In addition, the examiner has to take note of the wound corners, of concomitant bruises, and of all other features which may help to distinguish between lacerations, incised wounds, and other kinds of penetrating injuries. The condition of the wounds must also be assessed with regard to surgical treatment, infection, and signs of repair.

Similarly, other types of external injuries such as abrasions and bruises have to be reported with reference to their location, size, shape, and appearance. Sometimes characteristic details may be imprinted. In fresh abrasions, the skin tags sometimes indicate the direction of the blunt force. Bruising mostly concerns the subcutaneous layer, often in combination with intra-dermal extravasations (**Figure 1**); the latter are patterned if the

Figure 1 Bruise on the left thigh of a young woman from multiple blows with a looped extension cord.

skin has been pressed and squeezed into grooves (e.g., by the impact of a rubber sole). Parallel 'tram-line' bruises derive from the impact of a stick or rod, which is of special importance in suspected physical child abuse (Figure 2). Nevertheless, it should be emphasized that most bruises do not have any characteristic shape. Immediately after contusion, the skin need not show any changes of color; in cases of suspected blunt trauma, it is recommended to wait 1 or 2 days and to examine the victim a second time when extravasation has extended enough to become visible. It is well known that color changes occur within a few days so that the initially bluish-red bruise becomes greenish-yellow (Figure 3).

Some major points of external victim examination are specified in Table 2.

Injuries of Surviving Victims and of Assailants Following Attempted Manual or Ligature Strangulation

One of the common tasks of police surgeons and forensic medical experts is to examine persons who are supposed to or claim to have been strangled by hand or by ligature: for instance, in sex-related offenses such as rape, in attempted

Figure 2 'Tram-line' bruises on the right hand and forearm from beating with a cane in a case of physical child abuse.

Figure 3 Surviving victim with numerous pellet injuries of the left upper arm and breast from a distant twelve-bore shotgun discharge without penetration of the thoracic wall.

homicide, and due to maltreatment in cases of domestic violence.

In manual strangulation, the pressure on the neck is exerted externally by the hand(s) or the forearm resulting in occlusion of the blood vessels and the air passages of the neck. Most victims exhibit typical skin marks from the assailant's throttling grip: discoid or confluent bruises from finger pads, abrasions from fingernails (crescent shaped or scratches), and erythematous markings (Figure 4). Nevertheless, there are some victims who do not show any external evidence though there really has been a serious strangulation: this may be true when the palm or forearm was placed over the neck and when a soft object, such as a garment or a pillow, was interposed during pressure. Prolonged gripping of the neck with concomitant occlusion of the cervical veins leads to congestion and petechial hemorrhages of the conjunctivae and on the facial skin, especially the eyelids (Figure 5). Radiographs of the neck may reveal fractures of the hyoid bone and/or the thyroid cartilage; the incidence of such fractures is correlated with the extent of ossification mainly depending on the age and sex of the strangled person. Surviving victims mostly complain of pain on swallowing, on speaking, and on neck movement. Other possible symptoms following attempted strangulation are unconsciousness and sphincter incontinence.

In ligature strangulation, the pressure on the neck is effected by a constricting object (telephone cord, nylons, stockings, belt, towel, scarf) tightened around the neck by a force other than body weight. The appearance of the skin mark is influenced by the nature of the ligature (width, roughness, surface pattern), the force and duration of the strangulation, and the interaction with a resisting victim (displacement of the noose in attempts to remove it). The ligature mark usually encircles the neck horizontally (Figure 6); in typical cases, the skin reveals a transverse streak-like reddening caused by local erythema often associated with (partial) loss of the epidermis (Figure 7). Congestion and petechial hemorrhages above the ligature are usually more impressive than in victims of manual strangulation. On the other hand, damage to the hyoid or to the laryngeal cartilages is less common.

Suspected assailants may present examination findings indicative of possibly having been the offender in an attempted strangulation. The most frequent injuries seen in throttlers are nail marks inflicted by the opposing victim. Nail marks have been classified morphologically into three types: impression marks, claws, and scratches. The majority of the skin lesions are located on the dorsal aspects of the forearms and hands; other classical sites are the face, neck, shoulders and anterior chest wall. Another typical kind of injury, especially seen in rapists, is bite marks on the hands. If a struggle takes place, the assailant may sustain nonspecific blunt trauma from blows or from wrestling with the victim.

Medical Hazards in Police Custody

Even in countries with a high standard of health care of detainees, some deaths do occur in police cells and in prisons. A large number of custodial deaths are due to natural causes, mainly from cardiovascular diseases, which account for the great majority of sudden and unexpected deaths. Another

Table 2 Important external findings in physically injured victims of criminal assaults

<i>Body region</i>	<i>Findings</i>	<i>Kind of traumatization</i>
Head	Excoriation	Blunt trauma to the soft tissues (e.g., kicks, blows from fists, flat hands or weapons, striking of the head against hard surfaces)
	Bruising	
	Laceration of the scalp or face	
	Bleeding from the ear	
Neck	Bleeding from the nose	Closed blows to the ear, fracture of the base of the skull
	Petechiae in the eyelids, conjunctivae and facial skin	Contusion or fracture of the nose, fracture of the base of the skull, severe strangulation
	Bruising or laceration of the lips, loose or damaged teeth	Manual strangulation, ligature strangulation, traumatic asphyxia
	Discoïd bruises, fingernail marks, scratches	Blow to the mouth
Trunk	Ligature mark	Attempted manual strangulation
	Intradermal bruising from folds of cloth	Attempted ligature strangulation
	Incised wounds	Neck holds or locks
	Abrasions, contusions	Sharp force (cuts, slashes, stabs)
Limbs	Tram-line bruising	Blunt trauma
	Patterned abrasion or intradermal bruising	Impact of a rod or similar object
	Bite marks (two opposing bruises/abrasions) from the dental arches	Impact of an object with a profile surface (e.g., rubber sole)
	Brush abrasion ('grazes')	Bites (child abuse, sexual assault)
Limbs	Penetrating wounds:	
	● Incised wounds	Tangential contact with a rough surface (caused by dragging)
	● Shot wounds	Sharp force (stabs)
	Fingertip bruises (especially on the medial aspect of the upper arm)	Projectile trauma
Limbs	Stab wounds and cuts (defense injuries)	Gripping or prodding
	Bruises and abrasions on the back of the hand and on the outer sides of the forearms (defense injuries)	Knife attacks
	Circumferential contusions of the wrists or ankles	Attack from blunt instruments, fists, or feet
		Restraining by handcuffs, tying of hands or feet

**Figure 4** Neck of a rape victim with roundish bruises and scabbed abrasions from survived manual strangulation.**Figure 5** Petechial hemorrhages on the skin of the eyelids.

category of fatalities concerns suicides, mostly committed by hanging. In prisoners with suicidal tendencies, it is therefore recommended to remove any objects that could be used for strangulation like belts, ties, stockings, and bootlaces. In spite of all precautions of the custodians, some detainees manage to find devices suitable for strangulation such as strips of bedding material or clothing.

Wrist cutting is another self-injurious behavior frequently seen in police custody, either as (attempted) suicide or as self-harm without intention to die. Incised wounds may be inflicted with any sharp-edged instrument such as a piece of glass or sheet metal from a tin. Risk factors associated with self-injurious behavior include the custodial setting itself (especially in isolation cells), being under the influence of alcohol and drugs at the time of incarceration, the availability of means for self-destructive behavior and many others.

A detainee who is suspected of being drunk and/or drugged at the time of committal needs particularly close observation. If the prisoner has consumed a large quantity of ethanol or (illegal) drugs just before arrest, he or she may be conscious and responsive at first, but may become comatose later and die from acute alcohol or drug poisoning while he or she is erroneously thought to be sleeping off the drunkenness. This is not only true for ethanol ingestion but also for narcotic drugs (mostly heroin, methadone, and codeine). The victims do not necessarily die from the depressive effects upon the brain (especially the respiratory center); in a high percentage, a secondary aspiration of vomit is found as the immediate cause of death.

Alcohol is an important causal factor in aggression and violent resistance frequently leading to the arrest of the suspect.

Figure 6 Sharply defined ligature mark encircling the neck; the victim had been strangled with a shoe-lace 3 days before examination.

Physical overpowering of an offender involves the risk of inflicting injuries. In other cases, the person concerned may have sustained injuries due to falls or assaults before the police officers could intervene. It has to be stressed that even a fatal blunt trauma is not always associated with externally visible signs such as bruises, abrasions, or lacerations. The authors had to give opinions on several custody deaths due to blunt head injuries without any wound or palpable swelling; the (deep) bruise on the site of impact became visible only when the inner aspect of the scalp was inspected during autopsy.

Severe and ultimately fatal head injuries need not be associated with unconsciousness in the early posttraumatic period. In persons developing an epidural or subdural hematoma, the symptoms due to the elevated intracranial pressure may set in only after a 'lucid interval' of several hours so that they are falsely thought to be uninjured. From this it follows that cases of suspected cranial trauma require close observation and the possibility of rapid transfer to a hospital.

Torture

According to the 1975 Tokyo Declaration of the World Medical Association, torture is defined as the deliberate, systematic, or wanton infliction of physical or mental suffering by one or more persons acting alone or on the orders of any authority, to force another person to yield information, to make a confession, or for any other reason.

Torture has to be criticized as a particularly reprehensible offense against human rights; nevertheless, it does exist in numerous countries throughout the world. Within the scope of this overview, only a few medicolegal remarks on the physical manifestations of torture can be made. Unfortunately, often there is a long delay before medical examination so that conclusions as to the causation may be difficult because of the unspecificity of most scars.

Beating is probably the most common form of torture. Apart from kicks and blows from fists and flat hands, a great variety of weapons and instruments are used to inflict pain (e.g., rifle butts, clubs, and whips). When the body is struck by a rod or a similar object, each impact causes a double line of parallel

(a)

(b)

Figure 7 (a) Ligature mark from a solid-link chain tightened around the neck by twisting it in the nuchal region. The victim was a 13-year-old inmate of a supervised home. In the course of an argument, he was strangled by a 15-year-old fellow occupant until he became unconscious. Note the pattern of intracutaneous bruising reflecting the links of the chain (b).

bruises. Patterned abrasion or intradermal bruising may reflect characteristic details of the weapon's surface. Series of skin marks arranged in approximately the same orientation point to an unchanged position of the attacker in relation to the helpless (held or tied) victim. Heavy blows to the face are typically followed by periorbital hematomas ('black eyes'), extensive bruises and excoriation of the other facial regions, laceration of the lips and displacement of incisors, and fractures of superficial bones (nasal bone, zygomatic bone, jaws). The other main targets of beating and whipping are the back, the buttocks, the legs and the soles of the feet, the abdomen, the breasts and the genitals, which are also pinched and squeezed. Physical abuse other than blunt traumatization can only be mentioned briefly: cutting, piercing and stabbing, hair pulling, burning with cigarettes, repeated dipping of the victim's head under water, applying electric current, suspension, and sexual abuse.

DV Domestic violence

ED Emergency Department

Introduction

Domestic violence (DV), including intimate partner violence, is a worldwide phenomenon and a major public health issue. The mortality and morbidity caused by DV as well as its burden of disease are high. DV appears worldwide, affecting individuals in every community, regardless of age, economic status, race, religion, nationality, or educational background. In 1980, the Duluth Minnesota Domestic Abuse Intervention Project became a model for further interventions in many states and countries worldwide. Today, in all continents, ambitious efforts are being made by politicians, lawyers, social workers, and community leaders, and increasingly by medical specialists and forensic experts to combat this kind of violence, mostly against women. The WHO published in 2002 a comprehensive world report on violence and health as well as several studies on violence against women and organized an international network for prevention of violence. During the last few decades, first Canada and the United States, followed by Australia and many states in Europe, introduced new laws, hoping that DV would no longer be hidden in the privacy of the family, but would come out as a public affair. One example is 'The Violence Against Women Act' (www.womenshealth.gov/violence/legislation/), which supports communities in their effort to help protect victims and to educate perpetrators.

The US Department of Justice, for example, declaimed that "between 1993 and 2008, there was a 53 percent drop in the number of nonfatal, violent acts committed by intimate partners," maybe as a result of all these efforts.

Because of the increased interest related to law enforcement for DV, the importance of an optimal evidence-based criminal prosecution was raised in parallel. Experts in the forensic field have to coordinate their efforts to improve their knowledge of the characteristics and the diagnosis of DV, evidence collection, and the documentation of important signs of physical or sexual violence.

The following articles should help to improve this knowledge and provide a summary of the issue of DV for science and practice.

Definition

In the worldwide literature, DV is equated with violence against women. The United Nations defines violence against women as "any act of gender-based violence that results in, or is likely to result in, physical, sexual or mental harm or

suffering to women, including threats of such acts, coercion or arbitrary deprivation of liberty, whether occurring in public or in private life."

DV concerns not only women as victims but also men and children, and the perpetrators could be any member of the family. So the definition of DV must be expanded to include 'a pattern of abusive behavior in any relationship that is used by one partner to gain or maintain power and control over another intimate partner or member of the domestic unit. DV can be physical, sexual, emotional, economic, or psychological actions, threat of actions or negligence that influence another person. This includes any behavior that intimidates, manipulates, humiliates, isolates, deprives, frightens, terrorizes, coerces, threatens, blames, hurts, injures, or wounds someone.'

An important reason for maintaining the circle of violence is the perpetrator's ambition to keep his power and control over the victim. The Duluth Model of power and control suggests a patriarchal system as the basis for maintaining violence in families and partnerships. This model does not include male victims of DV, and men's organizations created an alternative model for female perpetrators (see: www.batteredmen.com/duluwomn.htm).

Epidemiology

The WHO demonstrated in their multi-country study that:

- Between 15% and 71% of women reported physical or sexual violence by a husband or partner.
- Between 24% and 40% of women said that their first sexual experience was not consensual.
- Between 4% and 12% of women reported being physically abused during pregnancy.

The 'End Violence Against Women (EVAW) Coalition,' United Kingdom, declaims on its website that DV is under-reported even when the phenomenon 'accounts for 16% of all violent crime and will affect one in four women in their lifetime.' Identical data are reported in countries with a low average income and in peaceful and wealthy countries such as Switzerland.

The home office statistical bulletin 2007 of the United Kingdom describes that DV had the highest rate of repeated victimization. More than one-third of the victims have been victimized more than once. Most often (in 87% of cases), males count as perpetrators. It is a crime very often reported; the authors of the bulletin estimate that every minute one case

of DV is reported to the police in the United Kingdom. The crime scene is almost always the home, but only a minority of cases is registered as serious. Nevertheless, DV can end fatally; the WHO reports that every year, 5000 women are killed by family members. In England and Wales, on an average two women are murdered every week by a partner. So DV, even though it is seldom a serious crime in the common sense of the law, is not a harmless phenomenon.

Data about male victims vary in the literature and it is discussed as a controversial topic. The fact is that male victims show significantly less severe injuries than female victims. For example, bone fractures and skull fractures are rarely seen in male victims in contrast to females. Houry et al. examined the differences between female and male victims and perpetrators using the 'Women's Experience with Battering Scale' on a Level 1 trauma center in 2008. The authors found a DV victimization prevalence of 22%. Generally, they found similar rates of victimization and perpetration in men and women. Some authors guess that the women who batter their partners do it often as a reaction to their own victimization experiences and that male victims suffer less from a loss of power and control in a violent partnership. This may explain why women show more symptoms of psychological stress, psychosomatic disorders, and depression after violent experiences. If a male victim of a physical assault by women is examined, the mechanism of self-defense for the female perpetrator has to be discussed. This is why it is always very important to examine both partners physically after an incident of DV to prove typical self-defense injuries (Figure 4).

Kimmel described the differences between female and male violence very systematically in his 2002 publication. The fact is that about 90% of the aggressive acts are performed by males, and the damages are much more serious when a man is the perpetrator.

Even so, for practice and science it is most important to also think about male victims of DV and to include them in prevention and screening programs (see below).

Risk Factors for DV

The highest risk factor worldwide is being a woman. Abramsky et al. analyzed the data collected by the WHO multi-country study on women's health and DV to identify risk and protective factors. The most important are:

- History of abuse. There is a very strong correlation between experiences of DV in childhood and DV in the partnership.
- Younger age of the women.

- Attitudes to support the husbands' beating.
- One partner having alcohol-related problems. Generally, alcohol and drug abuse. Already in 1999, Kyriacou had shown an increased risk for injuries in case of alcohol and drug abuse by men.
- Involvement of one partner in nonpartner violence; this means violence in a public area.

Characteristics of DV

Here it should be discussed why it is worth including a special article on DV in an encyclopedia of forensic sciences. In combating this harmful and expensive phenomenon and performing investigations in cases of DV, specialized knowledge is essential because of the following reasons (Table 1):

This table shows the very complex nature of DV. Interventions always require an interdisciplinary approach.

DV is seldom an isolated incident. Because of its typical pattern, also called the Circle of Violence, there is often a spiral-like escalating repetition of the violence.

Kyriacou et al. described the dynamics of the violent relationship as an imbalance of power, and the coercive control of one partner as a trigger of the escalation.

Phases of the circle of violence

Typically, the incidents of violence follow a well-defined dynamic. The circle may turn like a wheel with a certain regularity or like a spiral with an aggravating violence as a term of an exacerbating situation (Figure 1).

In times of harmony, the couple live in love and peace. But often, caught in the circle of violence, these periods become shorter and shorter. Only help from outside could break this turning wheel.

Criminal prosecution and punishment in a criminal sense may not be enough to break the circle. Education programs for the perpetrators as well as support for the victims are very important for a couple to learn how to live without violence.

All investigators in cases of DV and other professionals should understand the dynamics of this circle. Indeed, each professional may see the victim and the perpetrator at different moments, thereby sometimes holding contradictory opinions of the situation. Considering the different phases of the circle allows for a better collaboration between the police, the justice system, social workers, and medical officers, all professionally involved at different steps of the circle. Moreover, it is a very important instrument for risk assessment. When it is clear that the wheel is turning faster and faster, and when the violence is getting heavier, then a fatal outcome must be considered and corresponding procedures must be induced, such as an interdisciplinary, high professional-level risk assessment. Most homicides by partners are committed close to the separation or divorce of the couple. At such times, the assessment of risk is very important to avoid such fatal outcomes.

Diagnosis of DV

Screening

A retrospective assessment of medical reports in Switzerland by Klopffstein et al. showed an average proportion of 0.4%

Figure 1 The circle of violence.

Table 1 Differences between domestic violence and other interpersonal violence

<i>DV</i>	<i>Public (urban) Violence</i>
Victims are more often women than men	Victims are more often men than women
The perpetrator is more likely to be unique, a man well known to the victim	Perpetrator could be unique or multiple, of either gender, and often unknown to the victim
Repeated incidents. Rarely a singular incident	One or limited incidents
The place of incident is almost always the home	The place of incident is almost always a public place
Significant induced comorbidity such as psychosomatic disorders, unspecific pain syndrome, higher level of suicide, depression, substance abuse, gynecological problem, etc.	Limited 'collateral damage,' such as PTSD
Injuries often declared as 'accidental' and not as inflicted	Injuries are clearly declared as inflicted
Diagnosis of DV must be actively performed by the examiner	There is almost no doubt about the diagnosis of a nonaccidental injury
In most countries, relevant criminal prosecution with complete forensic documentation and evidence collection follows even when the injuries are superficial, such as bruising, hematomas, etc., and the incident is not reported as a serious crime	Criminal prosecution and complete evidence collection in most countries only in cases with serious injuries or with a special criminal interest
Children are often involved. They must be protected from former incidents and fatal outcomes	Normally no children involved
Combination of several forms of violence such as sexual, psychological, and physical violence	Delimitable forms of different violence
Risk assessment is important to prevent repeated violence, violence against children, retaliation by the perpetrator, and fatal outcomes	Risk assessment is important to prevent revenge process

**Figure 2** Injuries on different parts of the body (copyright Swiss Medical Weekly 2010;140:w1347).

documented female patients affected by DV. This figure is far below the proportions to be expected from more recent data. In her literature review, Olive notes a minimal prevalence of 6% of female emergency department (ED) patients; other studies report a prevalence of between 6% and 30% of female ED patients. In a prospective analysis, Dearwater et al. found 2.2% of an ED's injured female patients to be victims of DV. Studies on the prevalence of DV among the population worldwide report that every 4th to 5th woman could be affected by DV. According to this data, it is hypothesized that in the absence of screening, most of the victims of DV remain unidentified in medical settings.

Obviously, many medical doctors fear to ask about DV. That is why, first in the United States, and then in Europe, Australia and Canada, guidelines have been developed to screen for DV, for example, from 'The Family Violence Prevention Fund San Francisco.' Also, The American Academy of Family Physicians, the American College of Physicians, the American Medical Association, and the American College of

Obstetricians and Gynecologists recommend screening for DV. The Department of Health in England recommends that health professionals consider 'routine enquiry' of some or all women patients for a history of DV. In Australia, the 'Queensland DV Initiative Screening Tool' has been established by the Queensland Government. If there is no evidence for general screening benefits, a 'routine enquiry' and 'case finding' are largely recommended by medical instances, including by WHO. However, in any kind of procedure, it is very important to educate the involved professionals. They must be prepared for positive signs of DV and able to act appropriately and in an interdisciplinary manner.

Setting up regular screening leads to a higher prevalence of DV in a medical setting.

Pattern of Injuries After DV

1. The typical injuries caused by DV result from blunt violence, mostly subsequent to fist blows, less commonly from kicks.

Figure 3 Localization of the injuries in the region of the head and neck (copyright Swiss Medical Weekly 2010;140:w1347).

Figure 4 Bruises on the forearm as a typical sign of self defence (copyright University of forensic medicine at the University of Berne).

Not very often, the victims present lesions from weapons such as knives or gunshot wounds. Most often, it is the head that is affected, especially the facial region (Figures 3 and 5). Victims of assault-related injuries often displayed blunt violence injuries, and showed 13 times more head injuries than unintentional injury victims. There is a well-reported accumulation of head injuries in nonaccidental incidents.

It remains doubtful whether the localization and type of injuries alone can be considered as predictors or indicators of assault-related injuries, the predictive value being too faint. Localizations of injuries in relationship to the injured person's age could indeed lead to a significant predictive assertion. Allen et al. classified the body in different areas and found out that central areas such as the head, neck, and chest more often displayed wounds resulting from assault-related injuries. The limbs are more often accidentally injured.

From the forensic medical perspective, arm injuries deserve particular attention as probable defense injuries (Figure 4) above. To identify a self-defense injury may help to distinguish between the victim and perpetrator.

Special attention must be paid because of the danger to life. The character of an injury such as a kick in the face (Figure 5) or the use of weapons may allow one to draw conclusions regarding the intention of the perpetrator, such as impulsiveness or a feeling of disrespect for the victim. For example, when

Figure 5 Marks in the form of subcutaneous hematomas after a kick with a shoe. The marks show the sole of the shoe (copyright University of Forensic Medicine at the University of Berne).

the body is full of contusions, it is a sign of uncontrolled and impulsive violence, which at some time could lead to a fatal outcome.

Aspects for the Criminal Prosecution

Criminal prosecution of DV is possible only when the behavior of the perpetrator is defined as criminal under state law. For example, when physical violence is used or there are threats of such violence and it is clear that the potential aggressor can carry out the threats, the abuse is an assault. Emotional or financial abuse will not be prosecuted because it usually does not rise to the level of an otherwise defined crime (Table 2).

Partner violence does not often lead to severe injuries in the penal sense of the term such as injuries linked with a danger to life, a mutilation, or a disfigurement or lasting impairment. Even in 1999, Kyriacou et al. had shown in a case control study that the victims showed mostly contusions and abrasions, and only in 10% of cases were there fractures and dislocations.

Collateral harm such as psychosomatic disorders and other stress-related damage or a potentially dangerous situation that threatens to escalate is not usually considered in a penal

prosecution. That is why in most countries, DV is a crime of misdemeanor with a corresponding penal outcome.

Nevertheless, it is very important to proceed with a complete forensic investigation in cases of DV, so as to not miss hidden proofs of physical force and violence (Figure 6).

Strangulation is a special situation. It is often seen in violence against women. Most of the victims studied were strangled by an intimate partner manually. More than one-third of the victims described a history of DV. It is considered a danger to life if petechial hemorrhages can be proven in the facial skin, including the conjunctiva of the eye and other mucous membranes as a result of compression of the neck and obstruction of the venous return with continued arterial pressure and engorgement of the vascular system. To detect internal injuries as significant signs of a relevant strangulation, Yen et al. noted an increased accuracy with magnetic resonance imaging of the neck after strangulation. Classification of the

Table 2 Misdemeanor of crime under US Federal State Law (Original Text)

A 'misdemeanor crime of domestic violence' means an offense that: is a misdemeanor under Federal or State law; has, as an element, the use or attempted use of physical force, or the threatened use of a deadly weapon; and was committed by a current or former spouse, parent, or guardian of the victim, by a person with whom the victim shares a child in common, by a person who is cohabiting with or has cohabited with the victim as a spouse, parent, or guardian, or by a person similarly situated to a spouse, parent, or guardian of the victim. However, a person is not considered to have been convicted of a misdemeanor crime of domestic violence unless: the person was represented by counsel in the case, or knowingly and intelligently waived the right of counsel in the case; and in the case of a prosecution for which a person was entitled to a jury trial in the jurisdiction in which the case was tried, either—the case was tried by a jury, or the person knowingly and intelligently waived the right to have the case tried by a jury, by a guilty plea or otherwise

Figure 6 Small laceration on the inner side of the lips as the sign of a hit against the mouth. The teeth are like a skewback for the smooth mucosa of the lips (copyright University of Forensic Medicine at the University of Berne).

forensic estimation of the danger to life is more objective with the radiology approach. Not only are the legal consequences important, but a strangulation in cases of DV is also considered as an important predictor of a higher risk for a fatal attack and a coincidence of sexual violence.

Documentation

In all cases of DV, a complete and standardized medical report should be prepared for medicolegal purposes. Often, victims first avoid a criminal prosecution, but for future investigations it is important to have a detailed documentation from the beginning of the incident. It also protects the views and interests of the victims and improves the outcome of a criminal prosecution.

Standardized forensic medicine documentation is important for the purpose of legal equality and to ensure quality service to victims of violence who receive medical certificates.

Criminal investigation of victims of violence includes clarification of the following questions:

1. Has an offence been committed? Are there self-inflicted injuries, accidental injuries, or nonaccidental injuries?
2. What is the extent of the injuries? Are they superficial injuries, severe lesions, only in parts of the body or overall?
3. What is the age of the injuries? What was the time of the incident?
4. What is the cause of the injuries? Was there a presumption of a weapon being used?

In court proceedings, an expert should be able to provide answers to the above-mentioned questions without having examined the victim himself and only by studying the medical documents.

That is why a complete forensic documentation should include the following information:

1. Personal data
2. History, for example, information on the exact and complete circumstances of the offence, as related by the victim. Statements from the victim about threats, especially death threats or threats with an instrument, coercion, prohibition from making or receiving phone calls or leaving home, etc. are important to ask for and to be related with the victim's word. In addition, it may be important to ask for, and relate to, identical circumstances in the past.
3. Injuries:
 - a. Type (bloodshot, laceration, etc.)
 - b. Localization
 - c. Extent, size, dimension
 - d. Age of the injury
 - e. Shape
 - (a) The 'type of injury' category can be considered complete when a diagnosis is stated in the report (e.g., bruise, cut, scratch) or when the wound morphology, that is, the wound's edges, base, and surrounding area, allows a wound diagnosis to be established.
 - (b) Description of wound localization is considered sufficient when the injured part of the body can be located.
 - (c) Indications of size are met when the unit of measurement is given (usually cm).

Figure 7 Hematoma behind the ear as a typical nonaccidental injury (copyright University of Forensic Medicine at the University of Berne).

- (d) The wound's age is considered defined if it is evaluated in the report (recent, old, etc.) or if the wound's description allows a conclusion to be drawn.
- (e) The shape is considered given with a bidimensional description of an injury or with concrete indications of the shape.

In order to obtain the highest quality of forensic documentation, photos and sketches must show the following: localization, color, extent, and shape of the lesions.

Clinical forensic radiology may become very important for an objective and long-lasting documentation.

As mentioned earlier, even very small and inconspicuous lesions could be very important to differentiate the aggressor from the victim (Figure 6). In this figure, there is the mark of a hit against the mouth in the form of a small scratch on the inner side of the lip. So the region behind the ears should always be inspected to not miss possible hematomas after a hit on the head (Figure 7).

Sexual Violence and DV

Sexual violence concerns more women than men worldwide and is often a part of DV. For the perpetrator, rape is a means to get control over the wife or partner. In every investigation, it is a very important matter to consider, because for women it is not easy to talk openly about it. In screening programs, the investigators noted great shame in the victims when they had to answer questions on this issue. In forensic investigations, the documentation of even very inconspicuous lesions is very important to prove coercion. In every investigation, the victim should be treated with respect and understanding to avoid a secondary victimization.

Children and DV

Normal, healthy development in children requires a secure environment. In families with repeated outbreaks of violence,

the children are under enormous and constant stress. It is considered that every form of violence inside a family means psychological maltreatment of the child. The prevalence of children affected by DV is high and its negative impacts are well known. It is estimated that about 30–60% of the children in families with DV are exposed to child maltreatment. After a screening for DV in a pediatric primary care clinic, it was found that a high rate of psychological violence could have been shown when children experienced DV. A total of 12% of the families screened positive. Other studies pointed out that exposure to DV leads to significantly higher levels of behavior problems such as internalizing behavior with a higher level of suicidality or aggressive behavior. Maltreatment of pets by children can be correlated with inner familial violence.

There is a strong relationship between child abuse and child experience with DV and a higher lifetime risk for DV. To break the harmful circle of violence, children must be supported and empowered to lead a life without violence. To take them out of the family can cause feelings of helplessness, especially when the children know that their mother is still in danger.

The assistance of children with experience of DV requires high professionalism and experienced child health care specialists who can help victims of child abuse and neglected as well as traumatized children.

Conclusions

DV is a very complex field and requires an interdisciplinary approach. There are important differences between DV and public violence. These differences have to be considered when planning preventions, political measures, criminal prosecutions, and interventions in a medical and social setting.

Complete medical reports should be prepared even when there is no criminal prosecution initiated by the victim, because he or she is not yet ready to leave the violent relationship. The victim may initiate criminal prosecution later. In this prospective criminal action, documentation of former incidents will be of great interest and support to the victim. But criminal proceeding alone cannot resolve the problems in a violent partnership and family. Psychological and social interventions provided by specialists are required to break the vicious circle.

Sexual Violence

E Mützel, Institute of Legal Medicine, Munich, Germany

© 2013 Elsevier Ltd. All rights reserved.

Definition and Epidemiology

Sexual violence occurs all over the world. Terms like *sexual violence*, *rape*, and *sexual abuse* are commonly used synonymously; however, they describe many different acts. The World Health Organization (WHO) defines sexual violence as “any sexual act, attempt to obtain a sexual act, unwanted sexual comments or advances, or acts to traffic, or otherwise directed, against a person’s sexuality using coercion, by any person regardless of their relationship to the victim, in any setting, including but not limited to home and work.” It should be kept in mind that the medical, social, and legal definitions of sexual violence vary between and within countries. Rape is typically defined as physical violence against the body with coerced penetration of the vulva, anus, or oral cavity. During commission of this crime, the perpetrator humiliates and typically threatens the victim, either verbally or with a weapon.

Estimates of the number of sexual assault victims vary. Comparative re-analysis of the prevalence of violence against women and health impact data in Europe from Schröttle et al. indicates that one in three to five women have experienced physical force against the body perpetrated by their current or previous sexual partner. Of the European women who were questioned, 6–12% were victims of sexual violence committed by their current or previous partner. According to the 2003 WHO guidelines, between 6% and 46% of women have experienced ‘attempted or completed forced sex by an intimate partner or ex-partner at some time in their lives.’ It was found that 7–36% of girls and 3–29% of boys have suffered sexual abuse. Victims of rape are also elderly women, men, and institutionalized disabled persons. The estimated number of unreported cases among all groups cannot be specified but is presumably high. One of the causes is the varying definition of sexual abuse among countries and therefore data cannot be consolidated. Moreover, not all countries have a reporting system for sexual abuse.

Sexual abuse of children and adolescents can include a wide range of sexual activities with the direct or indirect involvement of the victim, including intercourse with the victim, touching the victim’s genitalia, and exposing the victim to pornography. The child or adolescent does not fully comprehend the acts and thus cannot give informed consent. Again, definitions of this crime vary among different countries.

In the case of rape, perpetrators are typically men, although women sometimes commit this crime. In the case of child sexual abuse, perpetrators are frequently men, and an increasing number of the perpetrators are adolescents and boys. Because child abuse is typically committed by family members, the perpetrator is often the victim’s father, step-father, uncle, grandfather, or brother.

Risk Factors

Many factors increase the risk that someone will be raped. Although every person could be raped, some individuals are

more vulnerable than others. These include single, unaccompanied women; physically and mentally disabled persons; individuals with drug or alcohol problems; and victims of war. There are likewise a number of risk factors that make children or adolescents more vulnerable to sexual abuse. These include being female, having a physical or mental disability, coming from a broken home, having parents who were themselves abused, and having parents with drug or alcohol problems.

Forms of Sexual Assault

Rape

The type of sexual assault depends on the relationship between the perpetrator and the victim and on the perpetrator’s motive. The following are examples of situations in which rape can occur:

- rape by an intimate partner;
- rape within dating relationships;
- rape by a stranger;
- rape of women of all ages, but especially elderly women;
- rape of disabled persons;
- rape within marriage;
- rape during armed conflict.

Often, the motive of the perpetrator is not sexual desire but the need to demonstrate power and display rage. Such violent assaults typically occur between persons who know each other and so it is often jealousy, fear of dissolution of the relationship, or unrequited love that leads to sexual assault.

Child Sexual Abuse

Child sexual abuse can be ‘hands-on’ or ‘hands-off.’

Hands-on offenses are sexual acts with physical contact, such as:

- touching or stroking the body or genitalia;
- sexual penetration of the child’s mouth, vagina, or anus;
- inserting objects in the child’s vagina or anus; or
- masturbating in front of the child.

Hands-off offenses are sexual acts without physical contact, such as:

- the production of a pornographic film with a child;
- exhibitionism;
- verbal sexual violence; or
- watching pornographic films with a child

Sexual violence can occur in virtual environments through cyberbullying. Cyberbullying occurs within a community or peer group when sexual information about a victim is distributed using digital means. This information, typically pictures,

can spread very quickly through SMS messages, MMS messages, e-mails, chat rooms, and websites.

Online chat rooms provide men with an opportunity to prey on underage girls and can be a great danger. Older men who stalk these chat rooms describe themselves as younger than they are, or of the same age as the child or adolescent, to gain the victim's confidence. The purpose of this 'cyber grooming' is to manipulate the victim into meeting the perpetrator face to face.

Examination

Examination of Adults

General aspects

Forensic and clinical examinations should compile a complete record of injuries and all available evidence while being cognizant of the victim's physical and emotional needs. When interviewing or examining the victim, the examiner should be patient and open, but also objective and neutral. The top priority of an examination should be to protect the victim from further trauma. This requires the support of both the social support network and health and medical care systems; these systems, however, vary greatly among countries and do not always provide the medical and emotional support needed by sexual assault victims.

Physical and genital examination

Before examining the victim's body, the examiner must know the victim's account of the crime in detail to ensure that the account, the injuries, and the evidence are consistent. Some important questions to ask when interviewing the victim include:

- Who was the perpetrator?
- When did the rape take place (to determine the interval between the rape and the examination)?
- Where did the sexual assault take place (e.g., on the floor of a room, in bed, outdoors, etc.)?
- What violence (including bites, kisses, or licking) occurred?
- Did the victim resist?
- Did ejaculation occur, and if so, where?
- Were the persons involved under the influence of drugs or alcohol?
- Did the victim clean her or his body after the assault occurred, and, if so, what were the methods used?

With regard to the rape of a woman, special questions about contraception and communicable diseases complete the anamnesis. Depending on the interval between the sexual assault and the examination, the morning-after pill should be dispensed, blood tested for HIV and hepatitis, and swabs taken to test for venereal diseases. Sometimes, when a female victim was raped by a stranger and has sexual intercourse with her consensual intimate partner a short time before or after the sexual assault, different traces of sperms or a mixture could be found in the DNA. The anamnesis should therefore include details about the last voluntary sexual intercourse. A careful anamnesis also includes questions about the victim's gynecological history.

Table 1 Typical signs of extragenital injuries

Typical signs of extragenital injuries

Neck (strangulation, petechiae, love bite)
Hematomas at the inner thighs
Scratches at the buttocks and breasts
Bites at the breasts
Fingerprints on the upper or lower arms

Generally, the physical examination should involve all parts of the body. To help the victim, the examiner should ensure that the examination is done by a person of the same sex; if this is not possible, the examiner should have an assistant of the same sex nearby. Care must be taken to ensure that the victim does not undress completely, but only partially, to enable examination of one naked part of the body after the other. The injuries should be documented in words and pictures.

There are some typical extragenital injuries (Table 1).

After the extragenital examination, a genital examination should occur. Ideally, the genital examination should be performed by a forensic expert in cooperation with a gynecologist. The examination should take place on the gynecological chair; only persons with a physical disability should be examined on the examination couch.

For inspection of the external genitalia, the labia majora and minora will be spread, and then pulled forward and down with the fingers (separation and traction). The inspection of the hymen occurs in this position. Normally, the hymen can be brushed from the inside to the outside with a cotton swab; an investigation with a speculum is necessary only if there is a hemorrhage out of the vaginal canal or there are foreign objects inside. Use of a speculum may create difficulties, because the speculum blocks the view of the hymen, preventing an existing injury from being seen. The speculum itself may injure the hymen, making it impossible to distinguish between an injury caused by sexual intercourse and an injury caused by the speculum.

The following are typical genital injuries:

- defloration of the hymen,
- tears of the hymen or vaginal vestibule, and
- scratches and tears at the labia.

However, victims typically do not have genital injuries after a sexual assault.

During the examination on the gynecological chair, genital swabs from the vaginal canal or portio can be taken, as well as swabs to determine the presence of venereal disease. During the examination of the vaginal canal, accumulation of secretions, injuries of the vaginal canal or the portio uteri, fresh bleeding, and foreign objects can be discovered. If there are hemorrhaging injuries, an operation should follow immediately. Using an abdominal ultrasound and/or a vaginal ultrasound examination, injuries or bleeding inside the abdomen can be excluded. If necessary, other diagnostic or surgical measures can be taken.

The inspection of the anus happens in the same position as the inspection of the vagina, though the buttocks are spread

Table 2 Changes of the hymen depending on the influence of hormones. The development of the hymen differs in individuals. Therefore, the hormone-dependent hymen configuration change has a flowing time parameter

<i>Hormone-dependent developmental changes of hymen</i>	<i>Stage of newborn</i>	<i>Hormone-free period (unestrogenized state of the prepubertal years)</i>	<i>Prepubertal period</i>	<i>Pubertal period</i>
Age of life	<3rd week	3rd week to ~8th year	≥8th year	>Menstrual period

apart for a certain time, during which the anal sphincter can dilate, allowing the anus and anal canal to be inspected. The anal folds, pigmentation, and possible scars, injuries, and bleeding should be examined.

If there are major psychological problems because of the vaginal inspection or because of pain, conducting an examination under anesthesia should be discussed with the victim. If possible, the examination should be done without anesthesia, as it can change findings of the vagina or anus because of relaxation of the muscles.

If necessary, blood and urine should be tested for alcohol or drugs, both of the victim and, when possible, the perpetrator.

After a report is filed, the police can secure evidence from the perpetrator. Especially after a rape, the examiner should be aware that swabs of the penis can be used to search for biologically female particles in the DNA analysis.

Securing evidence

After sexual assault, various bits of evidence can remain on the body of a victim, including sperm and seminal fluid, saliva, and skin particles. This is the evidence that can be secured most frequently. Combing out pubic hair is also considered a general measure to secure traces.

To secure sperm or seminal fluid, the examiner has to know whether and where ejaculation took place. It is not self-evident that ejaculation occurred during the sexual assault. To secure sperm or seminal fluid, the examiner must use DNA-free swabs with or without a special transport medium. If ejaculation occurred in the oral cavity, the swabs should be brushed against the cheek pouches. With regard to the anamnesis of the victim, vaginal swabs are mainly taken from the posterior vagina fornices and the introitus vaginae. Swabs of the anus should be secured with caution, as they can be painful. For securing sperm and seminal fluid, several cotton swabs (ideally three or four) should be used at once.

The period during which sperm can be detected in the vagina is 4 days, though usually this period is shorter for microscopy, perhaps 48–50 h. If sperms cannot be detected under the microscope, the y-chromosomal marker on the cotton swab can be investigated.

The period during which sperms can be detected in the oral cavity and in the anus is shorter, 12–24 h; in practice, however, they are rarely found there. After an ejaculation in the oral cavity or in the anus, victims frequently clean their mouth or anus, destroying the evidence.

If no sperms are found, the perpetrator may have an azoospermia or have been sterilized. In this case, the prostate-specific antigen or the prostatic acid phosphatase can be investigated through immunochromatographic tests. If the tests are positive, a DNA analysis may be carried out.

Table 3 A few normal variants of the hymen

Normal variants of the hymen

- Annular hymen
- Crescent-shaped hymen
- Septated hymen
- Cribriform hymen
- Microperforated hymen
- Imperforate hymen
- Atresia of the hymen

Examination of Children and Adolescents

General aspects

The well-being and health of the child or adolescent is the top priority during an examination. The examination should be conducted in a gentle manner and with patience. A victim should never be forced to undergo an examination. When examining a child or adolescent, the presence of a parent or guardian is necessary. The younger the child, the more important is the attendance of a parent or guardian. The examiner should be aware that the person accompanying the child could be involved in the sexual abuse.

The examiner should be qualified in how to examine the victim and how to interpret the findings. He or she should be aware of the hormonal influences and therefore of the development of the genitalia, especially the hymen (Table 2), their normal variants, and the endocrinology (Table 3). Newborns have their mother's hormones in their body until perhaps the third week postpartum. After that, the hormone-free period begins. During this period, the hymen is transparent, thin, and prone to damage. From the eighth to ninth year, the child's own hormones (estrogen) begin to influence the genitalia (prepubertal and pubertal period). The hymen thickens, wrinkles, and becomes stretchable. From the beginning of these changes of the hymen, a vaginal penetration by a penis is possible, potentially without causing injuries.

Getting a report of the crime is important, but the younger the child, the more difficult is the questioning. A toddler is suggestively influenced through questions; therefore, it is often best to allow specially trained personnel to conduct the questioning.

Physical and genital examination

The examination by an expert includes the inspection of the whole body and after that the genitalia. The inspection of the whole body should signal to the victim that the examiner is interested in the patient in his or her entirety and not only in the victim's genitalia, which will relax many young victims.

The investigative technique depends on the age of the patient and also on the hormonal influence of girls. A toddler (who is free of hormones) can be examined while sitting on the lap of a parent or guardian, who can hold and spread the legs of the toddler. In this position the labia majora and minora, the introitus, the hymen, and the anus can be inspected. The examination of an older girl in the hormone-free period can take place on the examination table, first in the supine position and after that in the so-called frog-leg position. A girl in the prepubertal or pubertal period can be examined in the gynecological chair.

The inspection of the hymen of a girl in the hormone-free period has to be performed quickly and without causing pain. To ensure this, the labia have to be pulled forward and down (separation and traction) with the fingers. By contrast, the hymen of a prepubertal or pubertal girl is less sensitive to pain. In this case, a cotton swab can be used to display the hymen, facilitating the inspection of the margin. An inspection of the hymen with the speculum is contraindicated (see earlier), as is an examination under sedation.

A boy is to be examined on the examination bed, in a lateral position while bending the hip joint and knee joint. In this position, the buttocks can be spread and the anus inspected. The buttocks should be spread as long as possible to reach a reflexive dilatation of the anal sphincter. The penis is to be examined with regard to bleeding or other injuries, but the preputium should be withdrawn by the examiner or better by the boy himself.

Securing the evidence

A fluid like semen is difficult to collect. Generally, children and adolescents come to be examined long after the assault. Commonly, months or years lie between the examination and the sexual abuse. Literature describes that semen in the vagina of girls in the hormone-free period is detectable only for 9 h, perhaps 24 h, but no longer. For the securing of saliva or skin particles, see earlier text. For interpreting the findings of the genital examination, especially of the hymen, the so-called Adams' scheme (revision 2007) can be used.

Documentation

Independent of a report to the police, the anamnesis and all injuries should be documented in a standardized way. Generally, a documentation form can be used to simplify the process. This can also serve as an aid to memory at a legal proceeding later. The following are guidelines for filling out a documentation form:

- Descriptions of all injuries are to be written down exactly. That is, characterize the color, form, margin, dimension, and exact localization of the injuries. All injuries must be included.
- The injuries should also be photographed. A picture should be taken as an overview and then the injury photographed in detail with a scale. The photo should be taken at a right angle to the injury. If the photo is taken in an oblique projection to the injury, the injury itself may not be sufficiently visible.

- The report of the victim is to be documented exactly and in depth. Sometimes it is important to quote verbatim the words or sentences of the victim. Some victims do not understand words like ejaculation or erection. The examiner should speak clearly and should explain these words when necessary.
- Securing traces requires correct procedure. The examiner may find an explanation of how to secure the traces in the documentation form. Generally, the traces should be dry and clean.
- The injuries and the result of the traces should be interpreted carefully.

Case Management

A team assembled from various medical disciplines is needed to support a victim quickly and professionally. Conferences are to be organized by the head of the team, most suitably the social health worker from the clinic. Depending on the kind of sexual assault, some of the experts on the team have to meet for discussing the internal course of action.

The modus operandi of the health-care team depends not only on the kind of sexual assault but also on the health system. An expert who works in practice has to organize his health-care system by himself. Here, the approach is different from that in a clinic. The doctor in practice has to organize the network system from outside and know who the contact persons are before a victim of sexual assault appears in his or her practice. In a clinic, contact persons of the network system are noted through the social health-care system of the clinic itself.

Generally, if the victim is an adult, the discussion regarding what to do after the examination is restricted to the examiner and the patient. The adult patient decides, for instance, whether or not to file a police report. The social worker can help the victim learn about the methods available to protect herself or himself from the perpetrator in future.

If the victim is a child or adolescent, the discussion and decisions also depend on who the perpetrator is. If the perpetrator is within the family, the social worker should decide whether a report should be filed with the police or whether it is sufficient to take the perpetrator out of the family. These decisions depend on the findings of the examination: the clearer these findings are, the clearer is the course of action to protect the child or adolescent. The rules and legislation pertaining to this differ among countries.

Child Abuse

WA Karst, HGT Nijs, and RAC Bilo, Netherlands Forensic Institute, The Hague, The Netherlands

© 2013 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by R.E.I. Roberts & J.V. Evans, volume 1, pp. 368–374, © 2000, Elsevier Ltd.

Introduction

Child abuse is the physical, sexual, or emotional mistreatment, or neglect of a child. These broadly defined categories may overlap. In the United States, the Center for Disease Control and Prevention (CDC) and the Department of Children and Families (DCF) define child maltreatment as any act or series of acts of commission or omission by a parent or other caregiver that results in harm, potential for harm, or threat of harm to a child. Abuse can occur in a child's home, or in the organizations, schools, or communities a child interacts with.

Role of the Physician or Child Care Professional

Everyone involved in the care of children has a responsibility to recognize the possibility of abuse and/or to maintain the child's welfare. Assessment and investigation of suspected abuse is a multidisciplinary task, involving welfare agencies, health professionals, and the criminal and civil justice systems. For the medical part, preferably a child abuse physician is consulted in suspected cases.

The physician evaluating children who may have been abused is faced with many challenges. In addition to providing the diagnosis and treatment, the physician must also ensure the child's safety, assist in the collection of possible evidence, and report any suspected abuse to the state child protective services agency (depending on legislation).

Physical Abuse

Nonaccidental injury may range in its presentation from no discernable injury at all to a few bruises and scratches to a severely or fatally injured child. Several general 'red flags' in initial presentation with regard to child abuse are given in [Table 1](#). Training and support in the recognition of these 'red flags' is important to any health care professional.

Differential Diagnosis

It is important to exclude other possible explanations for the medical findings.

The differential diagnosis can be approached first in broad terms: make a distinction between a medical condition and trauma. Subsequently, in case of trauma, make a distinction between an accidental trauma and a nonaccidental (inflicted) trauma.

Take a full medical history and always complete a thorough examination ('head-to-toe' below 5 or 10 years of age). Beware of clustered or patterned (sometimes 'tell tale') injuries. Decide whether (non)accidental injury, carelessness, neglect, or

perhaps traditional cultural practice offers the most satisfactory explanation for the clinical findings.

The developmental stage of the child must be considered. A baby is not independently mobile, and a clear explanation is required for any bruise or injury (and a clotting disorder should be ruled out). However, accidents beyond imagination do occur.

'Those who cruise' (mobile children), are at risk by definition in acquiring injuries, especially in the front or over bony parts of the body. Some more specific 'red flags,' common patterns of injury in child abuse cases, are listed in [Table 2](#).

Common skin conditions mimicking child abuse should be carefully considered such as the Mongolian spot, juvenile striae or stretch marks, marks from coin rubbing (or other traditional practices), and dermatological conditions (e.g., erythema annulare, lichen sclerosis, impetigo, herpes zoster).

Aging bruises is possible to some extent. If yellow is present, the age of the bruise is at least 18 h (but not vice versa in the absence of yellow). Bruises may appear after only several days, may migrate dependent on gravity, and usually may remain visible for 1–2 weeks. Other injuries cannot be aged more than in terms of 'recent' or 'old' (yet, this distinction may be important from a forensic point of view).

Human bite marks characteristically show an oval or circular mark of two opposing U-shaped arches (in contrast with V-shaped arches from cats and dogs), including superficial puncture wounds and drag marks, and (petechial) hemorrhages. In addition, bites may be confused with skin conditions such as ringworm, erythema annulare, and pityriasis rosea. One must consider taking DNA swabs in a fresh bite and consulting a forensic odontologist.

In case of any suspicion of child abuse, a skeletal survey should be performed, especially in the young (below 5 years). Approved international protocols are available American College of Radiology (ACR) of Royal College of Paediatrics and Child Health (RCPCH). X-rays or other images should be reread by a (pediatric) radiologist with specific expertise.

Abusive head trauma (AHT) is the major cause of death after physical abuse, mostly in the first year of life. AHT occurs as a result of acceleration–deceleration trauma as in vigorous shaking (formerly known as 'shaken baby syndrome'), direct impact as in punching the head or throwing the child's head against a wall, or a combination of both. AHT is associated with retinal hemorrhages, encephalopathy, skin bruising, subdural fluid (blood) collection, (posterior) rib fractures, and so on, in various combinations and in various degrees. AHT may be present without any visible injury and with nonspecific clinical findings (breathing or drinking difficulties, vomiting). Therefore, the diagnosis of AHT is often not considered or missed initially. In many cases, not a single event has occurred but a series of events.

Table 1 General 'red flags' in initial presentation

(Unaccounted) Delay in seeking medical care
Other person than caretaker presents the child
Absent, inadequate, or changing explanation
Injuries of (clearly) different ages
History of previous injury
Failure to thrive
Parent shows little, or excessive, concern
Frozen watchfulness of the child

Table 2 'Red flags,' common patterns of injury

Any bruising on a baby
Clustered or patterned bruises or injuries (finger tip, grip, or pinch marks)
'Tramline bruising' or bruises carrying an imprint
Bruises not over bony parts
Finger marks/hand redness and weals ('slap mark')
Bilateral black eyes
Torn upper frenulum
Bite marks
Cigarette burns
Scalds and burns
Fractures

Accidental or birth-related skull fractures are typically single, narrow, hairline fractures, involving usually one bone (the parietal). The location of the fracture may not be the location of the impact because of pliability of the skull of the very young.

Nonaccidental skull fractures are typically multiple, complex, and branched. Skull fractures cannot be dated radiologically because of absence of callus formation (the margins of the fracture 'fade away' in months).

Rib fractures are usually without clinical signs (occult) and detected only on X-ray or CT-scan. They are seen most commonly in infants and young children. In infants without bone disease, the extreme pliability of the ribs implies that such fractures only occur after the application of considerable force when compressing the sternum toward the vertebral column (such as in an acceleration-deceleration trauma).

A negative X-ray should be repeated after 2 weeks. The presence of callus formation then indicates the presence of rib fractures, apparently former occult. Rib fractures, and long bones in general, may be dated radiologically to some extent (e.g., subperiosteal bone formation about 1 week, callous formation about 2 weeks).

Epiphyseal and metaphyseal fractures are injuries typical of nonaccidental injury. Pulling and twisting forces applied to the limbs, for example, during vigorous shaking, lead to shearing forces resulting in 'classical metaphyseal lesions.'

Several different types of fracture of different ages and in different sites may indicate multiple traumas clearly separated in time. Fractures may occur without any skin sign (such as a hematoma).

Burns and scalds are also commonly seen in physical abuse. Again, the explanation given in relation to the injury pattern is important to ascertain. Accidental scalds usually occur in a 'spill'-like fashion, typically leading to a scald affecting the

upper trunk and/or upper limbs or face. The scald may show an irregular edge, variable depth (with less depth in the periphery), flow-like pattern, and 'sparing effects' due to skin folds or clothing.

Nonaccidental scalds from hot water usually affect the trunk or lower limbs with or without involvement of the buttocks and/or perineum. Characteristically, there is a clear demarcation line (in a stocking manner for feet, or glove-like manner for hands). Nonaccidental scalds may be accompanied by other signs of child abuse such as fractures (often clinically occult). Therefore, a skeletal survey should be performed as a part of the medical work-up.

Nonaccidental cigarette burns typically form a circular or oval punched-out lesion 0.6–1.0 cm across, which heals with scarring because it involves the full thickness of the skin.

Severe other forms of scalding or burning may occur (e.g., caustic burns or deliberately contacting hot objects such as a steaming iron).

Again, also consider a differential diagnosis as several skin conditions may mimic burns (impetigo (bullosa), photodermatitis, hereditary skin conditions, and hypersensitivity).

Sexual Abuse

Child sexual abuse is defined as the involvement of a child in sexual activity that he or she does not fully comprehend, is unable to give informed consent to, or for which the child is not developmentally prepared, or else that violates the laws or social taboos of society.

Children can be sexually abused by both adults and children.

The prevalence of child sexual abuse is difficult to determine, because it is unclear that how often sexual abuse remains undetected. The worldwide prevalence is estimated at 20% among girls and 8% among boys. Studies using the law enforcement as well as victim self-report data found that more than 90% of the perpetrators of sexual offenses against minors were male. Strangers are the offenders in approximately 10% of child sexual abuse cases.

Child sexual abuse can sometimes result in physical harm, such as bleeding from lacerations or sexually transmitted diseases. Psychological harm is a far more common effect, however. Common psychological effects are depression, post-traumatic stress disorder, anxiety, poor self-esteem, and behavior problems including substance abuse and self-destructive behavior.

The Medical Examination

Clinicians should be aware of the importance of adequately obtaining the medical history in suspected child sexual abuse. It depends on local circumstances and legislation whether the history taking can be done without limitations. Often children's statements are more important for legal outcome than the medical findings.

It is important that a clinician who examines the genitals of a minor is familiar with the evidence regarding the interpretation of findings. The incorrect interpretation of findings can result in far-reaching consequences, not only if a finding is

incorrectly related to sexual abuse, but also if a relevant finding is not being recognized. If a clinician does not know how to interpret a specific finding, a consultation from an experienced colleague is needed before any statements are made. High-quality photo documentation, preferably using videocolposcopy, is strongly recommended because of the possible important role in consultation or for forensic purposes.

If acute sexual abuse is suspected (less than a few days ago), the child should be examined as soon as possible because of the rapidly diminishing chance to collect forensic samples and the rapid healing of lesions in the anogenital region. The likelihood of positive DNA sampling is highest within hours after the event and falls rapidly. Obvious genital injuries can heal within a few days, and even deep lacerations heal without scarring. Prophylaxis for sexually transmitted infections and emergency contraception also require a rapid assessment. In acute cases, the child must not be allowed to wash and all clothing and other relevant items must be retained unwashed till the examination (Tables 3 and 4).

Only clinicians with the ability to communicate comfortably with children about sensitive issues should perform the examination. It should be respected if children withdraw

consent for any part of the examination. The child should be allowed to choose who they wish to be present. If a parent or carer is unavailable or if an adolescent prefers to be examined without parent or carer, a chaperone should be present during the physical examination.

The physical examination should be performed from head to toe. The anogenital examination should be performed in supine frog-leg position with hips flexed and the soles of the feet touching. Young children might be examined on a carer's lap. It is recommended to examine prepubertal girls in prone knee-chest position as well. One should not use a speculum in prepubertal girls. In pubertal girls, a sterile Foley catheter could be used for demonstrating injuries in folds. The slightly inflated Foley catheter could be withdrawn from the vagina until the balloon rests against the internal aspect of the hymen. Using toluidine dye on the perineum and posterior fourchette might detect minor tissue injuries. However, minor tissue injury to these regions is a nonspecific finding for trauma and can be caused by other irritative and infectious conditions.

The Interpretation of Medical Findings

Genital Findings in Girls

Knowledge of normal variants of the genital area and the changes that take place in its appearance with age is indispensable (Figure 1). Common normal findings include redness of the labia and perineum, periurethral or vestibular bands, and congenital variants in the appearance of the hymen, including crescentic and annular. Urethral prolapse, lichen sclerosis, and failure of the midline fusion are conditions that are known to be mistaken for abuse sometimes.

The interpretation of medical findings starts with using appropriate and descriptive terms. Acute hymenal disruptions should be described as lacerations. Nonacute partial hymenal injury should be described as notches, and nonacute disruptions complete to the base of the hymen should be described as transections. Hymenal injuries heal rapidly and except for extensive injuries, can leave no residua (e.g., scars).

Accidental trauma could result in injury to the fourchette posterior or vestibule and bruising of the labia. The hymen will only be damaged if there is a penetrative component to the injury. Bumps, mounds, and tags of the hymen are common and are not the result of trauma.

When hymenal transections in the posterior portion of the hymen, hymenal lacerations, or extensive bruising on the hymen are found, penetrative injury should be strongly suspected. Superficial notches in the posterior hymen have been reported in abused and nonabused prepubertal girls. Deep notches in the posterior half of the hymen have only been reported in prepubertal girls with a history of vaginal penetration. In pubertal girls, posterior deep notches have been reported more often in girls with a history of vaginal penetration than in girls without vaginal penetration.

In earlier days, the hymenal width and the size of the hymenal orifice were considered important in the evaluation of child sexual abuse. It has been suggested that larger hymenal openings or narrowed hymenal rims imply that penetration has taken place. The fact is that larger hymenal openings and narrowed hymenal rims are nondiscriminatory for sexual abuse.

Table 3 Guidance on persistence of spermatozoa and other cellular material on skin, hair, and in body orifices following some sexual acts

<i>Sexual act</i>	<i>Persistence of semen or other cellular material</i>
Ejaculation on skin/hair	Up to 2 days
Penis in mouth	Up to 2 days
Vaginal intercourse prepubertal	Up to 3 days
Vaginal intercourse postpubertal	Up to 7 days
Anal intercourse	Up to 3 days

Table 4 Implications of commonly encountered sexually transmitted (ST) or sexually associated (SA) infections for diagnosis and reporting of sexual abuse among infants and prepubertal children

<i>ST/SA confirmed</i>	<i>Evidence for sexual abuse</i>
Gonorrhea ^a	Diagnostic
Syphilis ^a	Diagnostic
Human immunodeficiency virus ^b	Diagnostic
Chlamydia trachomatis ^a	Diagnostic
Trichomonas vaginalis	Highly suspicious
Condylomata acuminata (anogenital warts) ^a	Suspicious
Genital herpes ^a	Suspicious
Bacterial vaginosis	Inconclusive

^aIf not likely to be perinatally acquired and rare nonsexual, transmission is excluded.

^bIf not likely to be acquired perinatally or through transfusion.

Figure 1 The prepubertal vulva.

Genital Findings in Boys

Medical findings in sexually abused boys are less common than in sexually abused girls, and are not well reported in the medical literature. Genital injuries in sexually abused boys occur predominantly to the penis. Testicular or scrotal injuries are more frequently associated with accidental injury than sexual abuse. Acute lacerations or bruising of the penis are strongly suspicious for sexual abuse.

Anal Findings in Girls and Boys

Reflex anal dilatation, perianal venous congestion, and skin tags are seen in both sexually abused and nonsexually abused children. Reflex anal dilatation, which is a dynamic response of the opening of the anus due to relaxation of the internal and external sphincter muscles with minimal buttock traction, should be distinguished from anal laxity or reduced anal tone. Anal laxity has been described in sexually abused children, but there are no studies of anal laxity in children selected for nonabuse. Anal dilatation, which is not immediate and does not have an anterior–posterior diameter of 2 cm or more, is nonspecific. Chronic constipation, sedation, anesthesia, and neuromuscular conditions are more common causes for an immediate anal dilatation to a diameter of 2 cm or more than sexual abuse.

Perianal lacerations extending deep to the external anal sphincter are indicative of blunt force penetrating trauma. Lacerations or extensive bruising of perianal tissues are the result of acute trauma. Perianal lacerations should be distinguished from anal fissures, which are usually the result from constipation, and from the linea pectinata or dentata, which is normal anatomy and which could be commonly seen when examining a child.

Recording the Findings in Possible Child Abuse Cases

Findings should be recorded in writing and in images to enable discussion among professionals, peer reviews, education, and court procedures. Visual information should be photographed. Legal verification is required stating the identity of the child and the circumstances under which the photographs were taken.

In taking photographs, follow forensic standards in a standardized order to enable recognition of the affected body part and adequate (focused) close-ups at 90° to the surface with a measuring scale correctly applied.

Interpretation of Findings

The health professional should keep an open mind and assess any evidence objectively, considering all possible alternative explanations – whether in the course of court or otherwise ('fact finding').

Beware of the risk of overinterpretation, especially in cases of suspected sexual abuse (e.g., normal anatomy such as peri-urethral bands or a cribriform hymen has been interpreted as scars in a context of earlier sexual abuse). Also, underinterpretation is possible, especially in cases of AHT because of minor or nonspecific clinical signs.

This article is a revision of the previous edition article by S. Pollak & P.J. Saukko, volume 1, pp. 374–378, © 2000, Elsevier Ltd.

Glossary

Blank cartridge pistol A pistol with a cartridge containing gunpowder but no bullet, usually used for training, as a signal or for purposes of self-defense.

Laceration A wound/tear of skin and soft tissue resulting from blunt (but not sharp) force.

Introduction

The presence of defense wounds is justly considered an important sign that an individual has been the victim of an assault. Another aspect of medicolegal significance concerns the physical activity of the victim: defense wounds indicate that the attacked person was – at least initially – conscious and able to use his limbs for protection resulting in injuries to the forearms or hands or – in rare cases – to the legs. When sustaining defense wounds, the victim must have been aware of the assault (anticipating the blow or thrust) and fit for the natural reaction of protecting himself.

Defense Wounds from Knife Attacks

Such injuries are seen when the victim attempts to ward off a knife either by seizing it or by raising forearms and hands in order to protect other body regions (head, neck, and chest).

Traditionally, a distinction is made in the literature between ‘active’ and ‘passive’ defense wounds. According to this distinction, ‘active’ defense wounds occur when the victim grasps the knife with the hand with the injury then being located on the palmar side of the hand. The ‘passive’ wound type is sustained when the victim raises their hands or arms to protect the attacked body region; in this case, the injuries will primarily be located on the extensor side.

There are only a small number of papers available with detailed statements as to the frequency and distribution of defense wounds. The frequency of such wounds indicated for victims killed by sharp force usually ranges between 30 and 50%, and almost half of the victims (46%) who have survived a knife attack also show defense wounds. In victims primarily fit for reaction, the probability of the presence of defense wounds increases with the number of hits placed on the body.

If, in spite of multiple stabs, no defense injuries are found, it has to be considered that the victim may have been unable to react or impaired in his ability to defend himself already before the use of sharp force: for example, in knife attacks on a sleeping person, in unexpected assaults, and in victims made unconscious before the attack. The absence of defense wounds is also observed when the victim was held or tied. The same also largely applies to those cases where severe traumatization of a different type (e.g., by blunt force) occurred before the use

of sharp force. Moreover, it is to be expected that in cases of very high blood alcohol concentrations or under the influence of drugs, the ability to defend oneself adequately against an assault is reduced.

A study of a large number of cases with regard to the localization of defense wounds found about the same number of injuries on the flexor and the extensor side, often combined in the same victim. It seems justified to express doubts as to the stereotyped distinction between active and passive defense wounds. First, the various possible ways of stabbing with a knife must be taken into consideration. Different ways of moving the knife (in downward or upward direction) may produce defense wounds on either the extensor or flexor side of the arm. An injury on the extensor side of the limbs may also occur if the victim tries to seize the knife and the blade comes into contact with the back of the hand or the extensor side of the forearm.

In an attempt to grasp the knife, the fingers of the victim may close around the blade, which cuts across the flexures of the phalanges as the knife is withdrawn (Figure 1). In this case, several fingers may be injured by a single impact of the cutting edge sometimes even completely severing the flexor tendons. Another typical location is the web between the thumb and the index finger. Incised wounds of the hands are often ‘shelved’ so that one margin forms a flap of skin (Figure 2). Hand injuries are frequently located at the transition from the flexor to the extensor side of the fingers. Such wounds are typically encountered if the victim tries to protect himself by holding his hand against the knife with spread fingers.

It should be mentioned that in killed victims, more than two-thirds of all defense wounds are found on the left arm or left hand. This phenomenon has mostly been attributed to the fact that many offences start with the victim and the assailant being in an upright face-to-face position. In this case, the left arm of the victim will be nearest to the mostly right-handed perpetrator and thus will be injured more easily. This explanation is also supported by the fact that in killed victims, the left side of the body or trunk is more frequently affected by sharp force injuries. It has also been stated that the victim may unconsciously ward off an attack with the ‘weaker’ left arm in order to maintain the function of the right hand and arm, which is the ‘stronger’ one in most individuals. In this respect, it is important to know whether the assailant and the victim are right- or left-handed.

Figure 1 Two cuts on the palmar surface of the left hand caused by the cutting edge of a machete when the victim attempted to clutch the weapon.

Figure 3 Multiple cuts of the left forearm and hand sustained when trying to ward off a knife attack against the neck.

Figure 2 Defense wound of the right ring finger with beveled margin forming a skin flap.

Figure 4 Transfixion stab wound of the left hand after surgical treatment. The victim tried to fend off an attack with a kitchen knife.

There are a few special features regarding surviving victims of knife attacks: defense injuries are almost evenly distributed on the left and right arms, although the left half of the body – including the left upper arm – is again hit more frequently. Some victims surviving a knife attack show defense injuries, but no additional stab or cut wounds on other parts of their bodies. This may happen if the attacker uses the weapon primarily to threaten the victim or if he is severely handicapped in his ability to act, for example, due to the limited space available. In fact, it is to be assumed that the number of individuals injured in this way is rather high, but, as the experience in the courtroom shows, they are rarely examined by a forensic expert.

In rare cases, defense wounds are localized even on the legs; if the victim was in a lying position, he may have used his legs to ward off the knife or curled up in order to protect vital areas with his drawn-up extremities.

Stabbing actions do not necessarily result in actual stab wounds, but result in cuts if the blade contacts the curved surface of a limb tangentially (**Figure 3**). In transfixion stab wounds, the weapon passes through the soft tissues of an extremity and afterward possibly reenters another body region (**Figure 4**). Irregular, L-, Y-, or V-shaped stab wounds (**Figure 5**) and wounds combining cutting and stabbing characteristics (**Figure 6**) may occur due to relative movements between the assailant and the victim. Defense injuries to the limbs covered by garments are usually accompanied by corresponding damages/cuts in the clothing.

Defense Wounds due to Blunt Force

Defense wounds of this kind are seen in blunt force attacks when the victim attempts to ward off kicks, blows of the fist, or blunt instruments. Their location is similar to defense wounds from knife attacks (hands, forearms, or, less frequently, the legs). Injuries inflicted to the thighs possibly result from attempts to shield the genitals against blows or kicks aimed at the lower part of the body.

The injuries most often seen are abrasions and contusions (with concomitant bruising) on the back of the hands, wrists, and forearms (**Figure 7**). Though abrasions and bruises are the most common defense injuries due to blunt force, additional lacerations may occur in skin regions supported by bone (e.g., the metacarpal region and the knuckles). Lacerations from a blunt instrument possibly contain embedded foreign material indicative of the weapon used. Defense injuries inflicted together with wounds in the regions the victim wanted to protect with his hands and arms show the same stage of healing on later inspection.

In rare cases, the victim may sustain fractures of the hand bones. Another classical fracture site is the ulnar shaft, which is exposed in victims parrying a blow or kick with their raised forearm. Depending on the site of the causal impact, these fractures usually occur at the transition from the proximal to the middle third or in the middle third of the ulna.

Defense wounds due to blunt trauma deserve special attention in suspected physical child abuse. In such cases, bruises or abrasions may reflect patterned details from the instrument

delivering the blow (e.g., belt, stick, rod, heel of a shoe). In adults also, a great variety of blunt instruments can be used to inflict severe injuries, mainly to the head. If the hand is interposed in a protecting manner, it will primarily be hit by the weapon (**Figure 8**). By placing the hands on the top of the head, the victim tries to lessen the blows. Apart from typical blunt weapons as hammers, firm bottles, and wrenches, sometimes also (blank cartridge) pistols and revolvers are used for striking ('pistol whipping').

Defense Wounds from Other Weapons

Chop wounds are a special category of injuries due to sharp force by heavy instruments with a cutting edge such as axes, machetes, and meat cleavers. Such wounds are characterized by cuts of the skin in combination with sharp-edged notches or comminuted fractures of the underlying bone.

Figure 5 Irregular stab wounds on the dorsal and ulnar aspects of the right forearm: one of the stab wounds is extended by a superficial incision, and the other one is V-shaped due to twisting of the blade. The weapon used by the assailant was a survival knife.

Figure 6 Defense injuries on the forearm of a victim who was killed by stab wounds to the chest and cut-throat wounds.

Figure 7 Bruises on the dorsal face of the left hand of a female victim who tried to protect her head against fist blows. In addition, there is a shallow cut on the index finger (defense wound from a knife attack).

Figure 8 Defense injuries on the back of the right hand: excoriations, bruises, and a shallow laceration due to multiple blows with a pistol grip.

Figure 9 Entrance and exit wound of a caliber 0.32 bullet, which first passed through the right forearm (a) and afterward entered the chest (b). The victim had raised his arm when a burglar shot at him.

In a wider sense, even in firearm injuries, the upper limbs may reveal a special kind of defense wound when the victim raises an arm in an unsuccessful attempt to shield vital areas of the body. Under such circumstances, the bullet first passes through the hand or the arm and afterward often enters the head or the thorax producing a reentry wound (Figure 9).

Misleading Findings Similar to Defense Wounds

Superficial cuts restricted to the skin are sometimes found on the fingers of suicides who used double-edged razor blades for cutting their wrists or who injured themselves when positioning and fixing the knife used by gripping its blade (Figure 10). Most of these cuts do not pass through all layers of the skin so that differentiation from real defense wounds should not be difficult.

If a perpetrator stabs his victim using a knife without a guard, his bloody hand may slip from the handle onto the blade producing cuts on the palm or the fingers, which at first sight give the impression of real defense wounds. As a consequence, blood stains of both the victim and the assailant might be detected on the blade.

Heavy blows with the fist sometimes result in injuries to the assailant's hand, for instance, bruises or wounds from the victim's incisors or even fractures of the metacarpal bones.

The features of self-inflicted injuries are dealt with in a separate article. Hands and arms may bear multiple incisions from a preliminary suicide attempt, mostly localized across the front of the wrists and on the flexor surface of the forearms. The typical appearance is characterized by multiple clustered wounds, mainly in a horizontal and parallel arrangement, some being very superficial tentative incisions ('hesitation cuts').

Figure 10 Left hand of a 48-year-old woman who killed herself by cutting both of her wrists and by ingestion of prescription drugs. Superficial cuts on the index, middle, and ring fingers, and on the palm.

Apart from persons with a real suicidal tendency, numerous incisions are also seen among patients suffering from psychiatric disorders and in persons who want to draw attention to themselves ('sympathy cuts') particularly by making false accusation of assault.

Glossary

Factitious dermatitis A disorder in which patients intentionally inflict skin lesions on themselves, mostly by scratching or using sharp instruments.

Malinger This term refers to fabricating or exaggerating the symptoms of mental or physical disorders.

Munchausen syndrome A psychiatric factitious disorder which is characterized by feigning disease, illness, or psychological trauma in order to draw attention or sympathy to oneself.

Introduction

The physical examination of persons with injuries that have been self-inflicted deliberately is a part of the routine work in clinical forensic medicine. The recognition of self-harm is of criminalistic importance when differentiating between assaults, accidents, suicidal, and other kinds of self-destructive behavior; the main categories are listed in [Table 1](#). In cases of simulated offenses, early diagnosis prevents superfluous and inevitably unsuccessful investigations by the police and mystified worries by the public. In the context of this article, the chief stress is put on the medicolegal and criminalistic aspects of physical traumatization by the victim himself. Completed (fatal) suicides, nonaccidental poisonings, and self-induced bodily harm in psychiatric patients are dealt with in other articles.

Simulation of Criminal Offenses

This group comprises self-inflicted injuries of individuals who claim to have been the victim of an assault. The bodily damage, therefore, is used as an alleged proof of a fictitious offense. The dramatic story told by the informant is often in obvious contrast to a uniform wound pattern ([Figure 1](#)) and a poor severity of the injuries so that the whole picture does not suggest a real struggle with the dynamics of a fight.

According to the literature, up to 20% of the sexual offenses reported to the police are fictitious. In false rape allegations, the informants frequently injure themselves in order to give support to their story. Women and girls, who falsely claim to have been raped, often live in a problematic situation or in conflict with their partners. The primary intention of the alleged victims is mostly to derive attention, or care and affection, but there are also some informants who accuse a definite person of having raped them for motives of hate or revenge.

Usually the self-inflicted injuries are caused with the help of pointed and/or cutting tools such as knives, razor blades, nail scissors, and broken glass. The resulting wounds are of a trivial nature, mostly consisting of superficial cuts or linear abrasions. The characteristics of a 'classical' injury pattern are listed in [Table 2](#). In typical cases, there is a multitude of equally shallow lesions, which are strikingly uniform in shape, often orientated

in the same direction or in a criss-cross manner. The cuts avoid especially sensitive areas like the eyes, lips, nipples, and genitals. They are mainly located on the frontal aspect of the trunk, on the face, the neck, the arms and hands, and sometimes on the lower limbs. Nevertheless, self-inflicted injuries may also be found on the back of the body as far as it is accessible for the alleged victim's hand or if the injuries have been caused with the assistance of another person ([Figure 2](#)). Often the relevant garments are either undamaged or the damage does not correspond to the skin lesions.

Some women who claim a fictitious sexual assault inflict blunt skin injuries on themselves: for instance, linear excoriations produced by scratching with the person's own fingernails or by rubbing the skin against a rough surface. In rare cases, atypical findings such as contusions or singular cuts have been observed. As there are a few clinical reports on self-cutting after rape, the forensic expert has to be aware of uncommon self-destructive behavior, even in real victims with a posttraumatic stress disorder.

Apart from false rape allegations, there are some other categories of fictitious criminal offenses. Thus, an assault may be simulated and made credible by self-inflicted injuries in order to divert attention from the person's own theft or embezzlement. The authors have also seen several male 'victims' who claimed to have been stabbed or cut by perpetrators because they wanted to arouse compassion and regain the affection of their wife or girlfriend ([Figure 3](#)). In the last 20 years, an increasing number of informants cut swastikas, or other nazi symbols or words into their skin thus trying to gain sympathy as pretended victims of right-wing violence; if such incidents are covered in the media, they may be followed by an 'endemic' series of copycat acts.

Another possible reason for claiming a feigned assault is dissimulation of an attempted, but not completed suicide (e.g., in cases of nonfatal wrist-cutting). Injuries from autoerotic manipulation may also be concealed by concocting a story of criminal victimization. False allegation of kidnapping in combination with self-injury has been made by young girls and boys in order to excuse absence without leave. From the criminalistic point of view, it has to be considered that perpetrators may inflict injuries on themselves in order to represent a homicide as permitted self-defense.

Table 1 Main categories of self-induced bodily harm

- 1. Simulation of a criminal offense:
 - a. False rape allegation
 - b. Feigned robbery or alleged attack for other fabricated reasons
- 2. Self-mutilation for the purpose of insurance fraud
- 3. Voluntary self-mutilation and/or malingering among soldiers and prisoners
- 4. Dermal artifacts, self-mutilation, and malingering in patients with personality disorders
- 5. Suicidal gestures, (attempted) suicide

Figure 1 Group of mostly parallel skin lesions inflicted on the right cheek with nail scissors (23-year-old woman, who falsely claimed to have been the victim of a sexual assault; actually she wanted to arouse the attention of her unfaithful husband).

Self-Mutilation for the Purpose of Insurance Fraud

In this category of self-destructive behavior, an accident is simulated in a fraudulent attempt to obtain compensation from an insurance company. Usually the deliberate self-inflicted damage results in mutilation, that is, a substantial loss of a peripheral part of the body (mostly a finger or a hand). The instruments used for mutilation comprise sharp-edged tools such as axes, hatchets, meat cleavers, and cutting machines, various kinds of motorized saws, and, less frequently, blunt objects such as presses or conveyor belts.

Table 2 Typical features of self-inflicted injuries fabricated to simulate a criminal offense

- 1. Infliction either by sharp/pointed instruments or by fingernails
- 2. Equally shallow, nonpenetrating cuts or fingernail abrasions (sometimes each of considerable length)
- 3. Multitude of individual lesions
- 4. Uniform shape, linear, or slightly curved course of the lesions
- 5. Grouped and/or parallel and/or criss-cross arrangement
- 6. Symmetry or preference of the nondominant side of the body (usually the left)
- 7. Location in easily reachable body regions
- 8. Omission of especially sensitive body regions
- 9. No damage of the clothes or inconsistent damage
- 10. Lack of defense injuries
- 11. Additional presence of scars from former self-injurious behavior

Figure 2 Unclothed left deltoid region of a 14-year-old girl who pretended to have been injured by an unknown aggressor on her way home from school. Note the presence of several mostly parallel, shallow cuts in a location easily reachable for the dominant right hand.

Voluntarily inflicted injuries from axe blows are mostly claimed to have been caused by a misplaced stroke of the axe when chopping wood. In typical cases, the thumb or index finger is cut off completely in a right angle to its axis resulting in an isolated proximal finger amputation. In contrast, an

Figure 3 A 29-year-old right-handed man who inflicted cuts on his chest and left arm in order to gain the sympathy of his wife, who had engaged in an extramarital affair with a lover. Note the symmetric arrangement of the chest wounds, their parallelism, and uniformity. The whitish scars on the left forearm are due to former self-injurious episodes.

unintentional severance of the index finger is usually characterized by accompanying injuries to the adjoining fingers. In authentic accidents, the amputation is often a distal and incomplete one, taking its course in an oblique angle to the finger's axis. The same is true for accidents with power saws or milling machines (**Figure 4**).

It has been justly stressed that in finger injuries from heavy axe blows, a complete amputation is to be expected only if the severed finger was lying on a solid base serving as a support. A proximal and complete amputation of the index finger without concomitant injuries of the neighboring fingers suggests a so-called 'execution position,' which is extremely suspect of intentional self-mutilation (**Figure 5**). In the recent past, a considerable number of physicians – the majority being males over 40 years of age who worked in the surgical field – have been convicted of defrauding insurance companies by deliberately cutting off a finger, mostly the index finger of the nondominant left hand. Some reports have been published on cases in which members of medical professions applied a local anesthetic before injuring or mutilating themselves.

Figure 4 Left hand of a carpenter who injured himself accidentally when working with a milling machine. Note the oblique severance of the thumb and index finger. The distal phalanx of the middle finger was incompletely amputated and could be sewed on.

The proof of intentional self-infliction in cases of mutilation has been said to be one of the most difficult tasks in clinical forensic medicine. Apart from the medical aspects, some circumstantial indications may point to a possibly attempted insurance fraud: an insurance policy for inadequately high amounts taken out shortly before the injury occurs, a multiplicity of private accident insurance contracts, serious indebtedness of the policy holder, the absence of any witness, an inexplicable disappearance of the amputate, immediate tidying up of the scene, and removal of the biological traces. The presence of 'tentative cuts' adjacent to the amputation cut can be a positive morphological indication of deliberate self-infliction. It is recommended that the expert's investigation should first focus on the medical findings concerning the injury (photographs, surgical report, radiographs, and physical examination) and on the course of the alleged accident as described and demonstrated by the mutilated victim. In addition, the external circumstances at the scene, the mechanical properties of the causative tool, the distribution of bloodstains, and other available pieces of evidence must be taken into consideration. Some experts have also carried out simulating experiments to reconstruct the alleged accident mechanism, which then turned out to be or not to be consistent with the injury in question.

Figure 5 Self-mutilation for the purpose of insurance fraud. Radiograph of the left hand exhibiting a complete proximal amputation of the index finger at a right angle to its axis and without any injury to the adjoining fingers, allegedly caused by a misplaced stroke of the axe when chopping wood (Photograph by courtesy of Professor Barz.).

Voluntary Self-Mutilation and/or Malingering Among Prisoners and Soldiers

Autoaggressive behavior is a well-known problem in police custody and penal institutions. There may be different reasons for a prisoner to inflict injuries on himself: false allegations of having been physically maltreated by the police, the guard, or other inmates; the wish to be transferred to a hospital with less severe surveillance and increased chances of escape; as a correlate of a prisoner's low tolerance to stress. Common methods of self-harm under detention are cutting oneself with sharp instruments (for instance, a piece of glass, a razor blade, or a sheet iron), swallowing foreign bodies, and certain forms of malingering (voluntary provocation, aggravation, and protraction of disease by artificial means). Self-damage in prison covers a wide continuum ranging from amateurish tattooing and infliction of other skin lesions to life-threatening suicide attempts.

During war and sometimes even in peace time, soldiers may fabricate 'accidental' injuries in order to avoid duty on the frontline or in the armed forces generally. The deliberately induced damage is intended to make the soldier unfit for military service (for example, because of traumatic amputation

Figure 6 Multiple linear scars on the left forearm of a 31-year-old man with BPD (borderline personality disorder) and many episodes of self-cutting.

by shooting or cutting off fingers). Another kind of evading service aims at the pretense of sickness. By feigning a medical or psychiatric illness, the malingerer tries to get hospitalized or dismissed. Malingering comprises both the simulation of a nonexistent illness and the exaggeration/prolongation of an existing disease.

Artifacts in Patients with Psychic Disturbances or Mental Diseases

In neurotic patients, the main target of bodily harm is the skin, which may exhibit a great variety of lesions from scratching, pinching, squeezing, rubbing, and biting. The injuries are typically produced by the person's own fingernails, pointed/edged instruments, or rough surfaces. If the skin damage extends to the corium, it will heal with scarring, and occasionally, pigmentation. The majority of neurotic excoriations are irregular in shape and located in easily reachable body regions, such as the chest and the lateral aspects of the face, arms, and thighs, often with preference of the nondominant side (Figure 6). The coexistence of fresh lesions and different stages of wound healing, including scars, hints at repeated episodes of self-injurious behavior.

If patients pretend to be unaware of the real origin of their skin artifacts, this phenomenon is called factitial dermatitis. The mysterious disease is intended to draw attention to the emotional suffering of the patient whose personality structure is characterized by strong intrapsychic tension, inhibited aggression, depressiveness, and low frustration tolerance. Psychological tests yield severe autoaggressive tendencies. The spectrum of skin lesions comprises scratches, ulcers, thermal and caustic burns (e.g., from cigarettes or acids) (Figure 7), hematomas, and many others. Self-manipulation should always be considered when symptoms persist for a very long time in spite of adequate therapy.

Munchausen's syndrome is defined as a chronic factitious disorder with systemic malingering observed in adult patients who present themselves to physicians and hospitals with dramatic, but false stories of illness. In assuming the role of

Figure 7 Multiple self-inflicted cigarette burns of equal age (1 day) on the left forearm of a 72-year-old psychiatric patient with paranoid ideas (main diagnosis: chronic alcoholism and cerebrovascular encephalopathy).

physically ill patients, they submit to unnecessary medical procedures including invasive, painful, and even dangerous treatment. The factitious diseases are made credible by complaining of symptoms such as abdominal pain, bleeding from body orifices, dermatological changes, and acute neurological manifestations. In contrast, Munchausen syndrome by proxy is a rare form of child abuse in which a parent or other carer, usually the mother, brings a child for medical assessment and care. The proxy either invents a false illness story or really induces an illness (e.g., by nonaccidental poisoning, smothering, or inflicting physical injuries on the child).

Some mentally retarded or disturbed children show special forms of self-destructive behavior such as lip biting, head bumping, and grinding of the teeth. Psychotic patients may be capable of mutilating themselves in a bizarre and painful manner so that the appearance of the injuries is often inconsistent with the outlined criteria of self-infliction. Thus, medicolegal literature reports on self-amputations (fingers, toes, scrotum, penis), and also on enucleation of an eye and severance of the tongue.

Attempted Suicide

An attempted suicide is an action performed with the stated intent of jeopardizing the person's own life. An individual, who in desperation gives the appearance of wishing to commit suicide, but lacks the real intention to do so, makes a 'cry for help' or a 'suicidal gesture.' The methods of suicide attempts include the whole spectrum of intoxications and physical trauma: overdosed application of drugs, cutting and stabbing, jumping from heights or in front of a moving vehicle, gunshot injuries, electrocution, nonfatal asphyxia (Figure 8), burning, and jumping into water.

Figure 8 Survived attempt to commit suicide by hanging with an extension cord. The victim, a 39-year-old woman, was found with the buttocks supported on the floor. Due to incomplete suspension, only the weight of the upper part of the body contributed to the force exerted on the neck. Note the hyperemic hanging mark and the presence of multiple petechiae in the facial skin.

Figure 9 Left forearm of a young girl with dozens of linear scars from repeated self-cutting as suicidal gestures.

In the context of this article, only suicidal cutting and stabbing is discussed. Suicidal cuts are mostly inflicted by means of knives, razor blades, and other sharp-edged instruments. The flexor surfaces of the distal forearm, the cubital region, and the front of the neck are counted among the preferred 'sites of election.' The presence of linear scars may suggest previous attempts. Suicidal incisions are typically multiple, parallel, superficial, and arranged in groups. The shallow cuts, in particular, reflect the hesitant or tentative nature of the injuries (**Figure 9**).

In many suicide attempts, the individual abandons the method of cutting the wrists and/or throat after a few trial incisions and turns to another kind of self-destruction, which is expected to be more effective. In suicidal cuts of the wrists, the radial and ulnar arteries are severed only in rare cases. The left wrist is the most common target in right-handed persons, but about one-half of suicides cut both the left and the right wrist. In suicidal throat cuts, the incisions either pass obliquely across the front of the neck (for instance starting high on the left and ending at a lower level on the right) or the direction is rather a horizontal one. Again, numerous tentative cuts are regarded as a clue to self-infliction.

Suicidal stabbing is less frequent than cutting and usually confined to the precordial region and/or the neck. In both locations, the 'classical' pattern is characterized by grouped stabs without concomitant damage of the covering clothes. The wound slits in the skin are often parallel with the pointed end (produced by the cutting edge of the blade) always being on the same side. Similar to suicidal cuts, the existence of multiple trial stabs is accepted as a hallmark of self-infliction.

Glossary

Abrasion An area of skin or mucus membrane that has been superficially denuded secondary to mechanical force.

Achalasia Failure of the esophagogastric sphincter to relax with swallowing.

Active neglect Active neglect is the willful failure to provide care.

Contusion A bruise.

Decubitus ulcer A lesion of degenerating skin caused by pressure and decreased circulation resulting in hypoxia and ischemia of the tissues.

Dehydration The condition of a lack of proper body fluids either through decreased intake or excessive loss.

Dysphagia Difficulty swallowing.

Elder An individual 60 years of age or older.

Elder abuse Elder abuse is any abuse or neglect of a person aged 60 years or older by a caretaker or another person in a relationship involving an expectation of trust that threatens his or her health or safety.

Malnutrition Malnutrition, or bad nutrition, is the lack of a proper, balanced nutrient intake.

Neglect Neglect can be defined as a failure to provide basic care, goods, and/or services, which are necessary to insure physical and psychological/emotional comfort. It is also defined as the failure of a caregiver or other responsible person to provide for an elder's basic physical, emotional, or social needs or failure to protect them from harm.

Osteomyelitis Infection and inflammation of bone.

Osteopenia Reduced bone mass. The bone synthesis is decreased and unable to compensate for normal bone lysis.

Passive neglect Passive neglect is the nonwillful failure to provide care owing to ignorance on the part of the caregiver, his/her lack of skills, or the caregiver's own failing health.

Pathophysiology The disordered function of a body's physical and chemical process(es).

Patterned injuries Contusions or abrasions that recapitulate the implement used.

Pharmacokinetics The action of drugs or chemicals in the body over a period of time including absorption, distribution, metabolism, and excretion.

Physical abuse An action that is inflicted upon an individual with the purpose of causing injury and pain.

Proprioception Perception by sensory nerves that transmit information concerning movements and position of the body.

Psychotropic Exerting an effect upon the mind/brain; capable of modifying mental activity.

Scald A burn caused by hot liquid or steam.

Senile purpura Broad, geographic, flat, subcutaneous, red-purple hemorrhages in an elder resulting from minimal trauma due to the aging of skin structures such as dermal and vascular connective tissue.

Sexual abuse The act of contact with the mouth, breast, or anogenital area between an elder and the perpetrator; any sexual contact or exposure against an elder's will.

Starvation The condition of a severe lack of both nutrients and energy intake.

Xerostomia Dryness of the mouth.

As a result of the advances in medicine, science, and technology, people are living longer and living better. Such advances include tissue and organ transplantation, prostheses, microsurgery, pharmaceutical breakthroughs, and a better understanding of geriatric psychiatry and the aging body. Globally, the segment of our world's population 60 years and older, as well as individual life expectancies, is increasing. As of 2007, the life expectancy in the United States was 78 years, an all time high; for men, it was 75 years and for women, 80 years. However, with the increase in the number of older individuals, the demand for medical care has also increased, along with a growing need for public services and an increased number of older victims of abuse.

Elder abuse is any abuse or neglect of a person aged 60 years or older by a caregiver or another person in a relationship involving an expectation of trust that threatens his or her health or safety.

Six forms of elder abuse are recognized in the medical literature: neglect, physical abuse, sexual abuse, psychological abuse, financial and material exploitation, and violation of rights.

For the purposes of this article, an elder is any person ≥ 60 years and the focus is on physical neglect, physical abuse, and sexual abuse.

Age-Related Changes in the Body of an Elder

To understand elder abuse, one must first understand the common age-related changes. Many changes occur as the body ages. Some of these changes are natural or related to organic diseases, some due to lifestyle and occupation, while others are due to medical treatments and therapies. In the forensic arena, of significant importance are age-related changes of the skin and soft tissues, the musculoskeletal system, the central and peripheral nervous systems, and the gastrointestinal and urinary systems.

Skin

Many changes take place in the skin and subcutaneous soft tissues. The skin's moisture content decreases, partly due to

decreased sweat gland number and efficiency. The dermal-epidermal interface flattens, dermal mucopolysaccharides and collagen decrease, and the elastic and collagen fibers become stiffer. These changes predispose the elder to shearing injury, abrasions, and lacerations. The number of blood vessels in the dermis also decreases while vascular fragility increases. Senile purpura results from minimal trauma and develops quickly (Figures 1 and 2).

The lesions are flat, red-purple, and have a geographic border or configuration. They occur most commonly on extensor (hair-bearing) surfaces or areas of bony prominence. Sun damage, steroid use (steroid skin creams), radiation therapy, and blood thinners also predispose an elder to easy bruising and cutaneous trauma. Peripheral vascular disease, common in this age group, and diabetes mellitus affect the skin's circulation and healing capabilities.

Figure 1 Senile Purpura.

Figure 2 Senile purpura. Geographic, red-purple, flat.

Musculoskeletal System and Soft Tissues

With age, an elder has decreased adipose tissue throughout the body as well as muscular atrophy and a decreased number of myocytes and decreased muscle regeneration. Motor neuron denervation also occurs. Around the fourth decade, osteopenia and osteoarthritis manifest with increased bone resorption. Such degenerative changes are due to several factors. Inactivity, poor circulation, decreased hormone levels (especially estrogen and growth hormone), and decreased vitamin D production result in degeneration. The decrease in estrogen promotes increased bone resorption. Calcium is affected by parathyroid hormone, thyroid calcitonin, and calcitriol. Some elders have increased parathyroid hormone, which enhances bone resorption and mobilizes calcium from the bone into the blood. Many elders not only have decreased vitamin D intake, but they also have decreased conversion of vitamin D due to decreased exposure to sunlight and decreased calcium absorption from the small intestine. Joint flexibility is also decreased at this time adding to the risk of falls and bony trauma.

Central and Peripheral Nervous System

With age, the brain weight decreases due to cerebral atrophy, resulting in an increase in the size of the subdural space. In fact, in certain areas, the number of neurons decreases. Ischemic infarcts and degenerative changes further alter the cellular makeup and configuration of the brain. Gait, balance, and skilled motor movements become impaired due to decreased proprioception.

Acquired peripheral neuropathies such as diabetes mellitus adversely affect these functions, as can orthostatic hypotension, cardiac arrhythmias, and certain medications. Motor strength decreases as a result of a decrease in the number of motor neurons as well as the aforementioned muscular atrophy. These changes as well as certain medications, acquired coagulopathies, and increased falls result in a higher incidence of intracranial bleeds.

Elders often have impaired temperature perception and regulation resulting in a higher risk of hypothermia or hyperthermia. Heat production is decreased due to reduced muscle activity. Cutaneous temperature control is impaired by the decrease in the number of dermal blood vessels. Furthermore, the vasomotor response is less efficient, so both vasodilation and vasoconstriction are decreased. Elders also have decreased shivering due to a decreased shivering response and less efficient shivering.

Gastrointestinal and Urinary Systems

Elders have a decreased sense of taste and smell, decreased gastrointestinal motility, and early satiety. Certain medications can also interfere with taste. Salivary gland atrophy, smoking, and medications result in xerostomia. Xerostomia and receding gingivae predispose elders to infections and loss of teeth. Bone loss occurs around the teeth, and the roots become brittle and can fracture. Elders have decreased oromotor reflexes, decreased gag reflex, and a high incidence of achalasia and dysphagia.

Within the stomach, there is decreased secretion of HCl and enzymes. Decreased HCl results in decreased absorption of iron, folic acid, vitamin B12, and calcium.

Not only does such absorption of certain nutrients decrease due to age alone, but also malabsorption due to diabetes mellitus, hypothyroidism, or atherosclerosis. Gastrointestinal peristalsis is also decreased resulting in early satiety and prolonged drug absorption. Decreased large intestinal motility results in decreased water absorption. The kidneys have a decreased number of nephrons and possible atherosclerosis resulting in decreased water absorption, sodium loss, and decreased ability to concentrate urine. Constipation and fecal impaction is common in the elder population. Drug metabolism is affected by decreased gastrointestinal motility, decreased hepatic metabolism, and decreased renal clearance. Fecal and urinary incontinence are also common in this population, affecting maintenance of hygiene and pressure sores.

Who, Where, Why, When

Who: to detect, investigate, and prevent future cases of elder abuse, one must understand the players involved. Elder abuse occurs in all racial, socioeconomic, and religious groups. The typical victim of elder abuse is 75 years or older. Depending on the study, either no significant gender difference exists or females predominate. In the United States, most victims are Caucasian. The victim is not only known to the perpetrator but also has a personal relationship with the perpetrator. The victim often has inherent risk factors such as cognitive impairment, aggressive or disruptive behavior, physical impairment, poor health, incontinence, fear of institutionalization, loneliness, depression, or guilt. Therefore, the victim is dependent, or feels dependent, upon the perpetrator.

The perpetrator is usually a spouse or a child. Family members, adult children, or spouse are implicated in 90% of elder abuse cases. Studies have discovered three traits common to most perpetrators of elder abuse: mental illness or substance/alcohol abuse, emotional problems, depends upon the elder financially, and/or has a history of violence or exposure to violence or of abusing others. Seventy-five percent of perpetrators are less than 60 years of age.

Where: the acts of elder abuse most often occur in the home, either a house/apartment residence or an institution. The setting is one of isolation. Friends and neighbors will report that they have not seen the elder in some time or that they are not permitted to visit/gain access to the elder. The perpetrator lives with or near the victim.

Why: in many cases of elder abuse, there is a history of family violence. The elder victim may once have been the perpetrator of child abuse or spousal abuse; now he or she is the victim. This is termed generational violence. The perpetrator may be financially dependant upon the elder and uses the situation for monetary benefit. Such financial exploitation results in lack of proper care. The perpetrator may have a substance abuse problem that he/she must support, sometimes by use of the elder's own medications. The perpetrator may have a history of violent behavior, and the elder is an isolated target who will not, or is unable to, report such behavior.

When: sometime, there is no answer to the 'when' for elder abuse. If the above variables are present, then the abuse can occur at anytime. However, when examined, most of the acts of abuse occur during times of stress. The stress can be financial stress, emotional stress, or the stress of feeling forced to take care of a dependent, often difficult, elder.

Physical Neglect

The most common form of elder abuse is neglect. Neglect can be defined as a failure to provide basic care, goods, and/or services, which are necessary to insure physical and psychological/emotional comfort. It is also defined as the failure of a caregiver or other responsible person to provide for an elder's basic physical, emotional, or social needs or failure to protect them from harm. Such neglect includes isolation. Neglect can be active or passive. Active neglect is the willful failure to provide care. Passive neglect is the nonwillful failure to provide care owing to the caregiver's ignorance, lack of skills, or his/her own failing health. The distinction is not always clear, and a thorough investigation is needed to distinguish between intent to harm and actions of the uninformed, distracted, or misled caregiver.

When an elder is physically neglected, findings may include malnutrition, starvation, dehydration, lack of medical care, and poor hygiene.

Malnutrition, or bad nutrition, is the lack of a proper, balanced nutrient intake. Starvation is the condition of a severe lack of both nutrients and energy intake. Not only must a proper healthy diet be provided but it should also be served in the proper form (e.g., soft, pureed, assisted feedings) for the elder's intake and digestion.

Dehydration is the lack of proper body fluids either through decreased intake or excessive loss. Dehydration may be due not only to inadequate provision of drinking water or hyperthermic exposure but also to an altered thirst sensation in the elder, high-protein tube feedings, remote cerebral infarction, fever, and medications (Figure 3).

A lack of medical care includes poor diet based on medical condition (such as a diabetic diet), lack of medication, and lack of seeking medical treatment. The caregiver has a responsibility

Figure 3 Elder with a history of a fall/drop died of dehydration. At autopsy, a healing eschar was noted on the shoulder.

to seek medical care for the elder. Neglected wounds may become infected with flies and larvae bringing in the science of forensic entomology.

Poor hygiene may not in itself be fatal, but it is often a marker for other actions of elder abuse. Areas of poor hygiene include the teeth, nails, genitalia, and the immediate living environment. Within the mouth, untreated dental caries, excessive plaque, gingival lesions due to ill-fitting dentures, and long-term use of fractured dentures may be encountered.

One condition that is often associated with and is a red flag for neglect is the decubitus ulcer, also called pressure ulcer, pressure sore, or bedsore. In fact, it has been reported that 95% of neglect victims have decubitus ulcers. A decubitus ulcer is a lesion of degenerating skin caused by pressure and decreased circulation resulting in hypoxia and ischemia of the tissues. Decubiti develop because of immobility, prolonged positioning, friction/shearing, and incontinence and are enhanced by malnutrition, venous stasis, peripheral vascular disease, diabetes mellitus, and cachexia. Common areas for development are over bony prominences, the sacrum, inner knees, outer ankles, heels, and the occiput. Preventive measures and treatment include repositioning or turning the body every 2–3 h to remove pressure, provision of proper padding to bed and chairs, protecting lesions with proper dressing, frequent changing of bedding/diapers, wound cleaning, debridement, and antibiotics.

Many clinicians will grade decubitus ulcers on a 1–4 scale.

Grade 1 – nonblanchable erythema without a break in the skin

Grade 2 – superficial epidermal and dermal loss; partial thickness loss no deeper than the dermis. Intact subcutaneous tissue

Grade 3 – full thickness involving the subcutaneous tissue

Grade 4 – ulceration, full thickness with loss of skin and subcutaneous tissue and exposure of the skeletal muscle, tendon, and/or bone

The Department of Health and Human Services reported that over 10% of nursing home residents have pressure sores. Grades 3 and 4 are difficult to heal. The mortality of a grade 4 decubitus ulcer is approximately 50%. Sepsis results from subcutaneous and bone involvement. Osteomyelitis occurs in 17–58% of cases.

Physical Abuse

Physical abuse is an action that is inflicted upon an individual with the purpose of causing injury and pain. Acts of physical abuse include slapping, pinching, blunt force trauma, traumatic alopecia, burns, bites, improper restraints, and improper medication. Head trauma is the most serious type or category of physical abuse carrying the highest morbidity and mortality.

When evaluating physical abuse, the challenge is differentiating inflicted trauma from accidental trauma. As discussed, many age-related changes in the elder make him or her prone to accidental, noninflicted trauma or a condition that mimics abuse. It is common to see purpura, contusions, abrasions, and lacerations over bony prominences and over the extensor surfaces of the extremities. However, such injuries to the ear, face,

neck, inner thigh, back, axillae, or buttocks are worrisome for abuse. Also, various injuries over different planes of the body or appear to be of varying ages are suspect. Age-related changes in the bone put elders at risk for fractures. Fractures of the hip/femoral neck, proximal humerus, ribs (especially with cardiopulmonary resuscitation), and vertebrae are frequently encountered in the elder population. These fractures can be secondary to accidental 'minor' trauma and falls (**Figure 4**).

Falls as a result of medications, stroke, orthostatic hypotension, muscle weakness, poor foot care, poorly fitted shoes, improper walking aids or wheelchair fit, or during movement of an elder bed-to-chair occur. These fractures are usually in the cancellous bone next to a joint and rarely in the shaft of a long bone. With age, the chest wall is less elastic and rib fractures, pneumothorax, and hemothorax become more common. Simple rib fractures in elders most commonly result from falls. Pain from a rib fracture can result in decreased tidal volume, decreased ventilatory effort, decreased cough effectiveness, and complications such as pneumonia. However, other fractures such as those of the facial bones or skull, or fractures/dislocations that are not referred for medical evaluation (i.e., medical neglect) are suspect for abuse.

Patterned injuries recapitulating the implement used should be sought. Burns, contact and scald, are encountered in the victims of abuse. Scald burns of the extremities may have a glove or stocking distribution. Forced feeding due to impatience of a caregiver with an elder who has slow oromotor function can result in choking, 'café coronary,' and aspiration. Overmedication (see section '**Restraints**') or undermedication

Figure 4 Beneath the eschar was a recent, untreated fracture. The elder suffered medical neglect and dehydration due to neglect.

is a form of physical abuse. A caretaker may withhold pain medication for his/her own personal use or, due to financial reasons, a caretaker may not provide necessary medications needed for the elder's diseases.

Restraints

Physical restraints may be used for the safety and welfare of an elder. However, limiting movement can lead to muscle weakness and decreased physical functions. Restraints are worrisome if they are used without a medical evaluation. Signs of improper or prolonged restraint may be also identified. These signs include abrasions to the axillae, wrists, and ankles; decubitus ulcers from prolonged immobilization or restraint; loss of hair on arms from tape use; perioral facial abrasions from tape over the mouth; or fatal asphyxia from improper placement or 'off-label' use of a restraint device. Psychotropic chemical restraint may be used with elders who have dementia, are combative, or are agitated. Levels of psychotropic drugs can be detected pre-mortem or post-mortem through proper toxicological analysis.

Toxicology

Toxicological analysis can identify chemical restraint with a psychotropic drug as well as lack of prescribed medications. Blood must be collected in a vacutainer that contains a preservative such as sodium citrate or sodium fluoride. This is a gray-top tube in most institutions. Postmortem samples of blood should be from a peripheral site, the best source the femoral vein. Again, the blood should be collected into a vacutainer that contains the preservative. With age, total body water decreases with a proportionate increase in the fat content, or fat percentage. This results in an increased drug concentration in the blood and increased concentration of water-soluble drugs in the serum. Also, fat-soluble drugs will remain in the system longer with a longer half-life and take longer to reach a steady state. Signs and symptoms of drug toxicity can also be delayed. Decreased plasma proteins also result in higher free active unbound drug. Decreased hepatic mass, function, and blood flow as well as decreased renal excretion result in an increased bioavailability of drugs. Drugs that are normally excreted by the kidneys will accumulate. In short, the dosages and dosing frequencies of many drugs need to be altered with age.

Reasons for abnormal or suspicious toxicology results

Decreased total body water/fluid volume
Increased proportionate fat content, fat percentage
Decreased hepatic blood flow
Decreased gastrointestinal blood flow
Decreased plasma proteins
Decreased renal clearance
Decreased glomerular filtration rate
Decreased gastrointestinal motility
Decreased hepatic metabolism (pathway dependent)
Chemical restraint, intentional overdose
Prescribed medications withheld

Improper postmortem specimen
Improper vacutainer
Improper storage of specimen
Prolonged postmortem interval

Sexual Abuse

Sexual abuse, assault, or molestation is the act of contact with the mouth, breast, or anogenital area between an elder and the perpetrator. Sexual abuse is any sexual contact or exposure against an elder's will. The frequency of elder sexual abuse is unknown because of several factors including: cases are under-reported, investigators do not consider an element of sexual abuse when working with elder abuse victims, and medical personnel do not perform sexual assault examinations on elder patients or victims of physical abuse. It is a myth that an elder cannot or is not a target of sexual abuse purely based on the age of the individual. Sexual abuse and assault are acts of violence and control. Elders are victims as is any other age group.

The elder victim of sexual abuse is usually female. The victim often has decreased cognition, a fear of retaliation, and/or a fear of institutionalization. Again, the act is one of control resulting in underreporting. The perpetrator is most often male. The abuse occurs in the home/residence of the elder. Physically, the victim will often sustain genital and extragenital injury. The female elder victim is prone to genital injury because of decreased estrogen, atrophy of the vagina, dryness and thinning of the vaginal wall, and weakened pelvic structures. Extragenital injuries include those previously mentioned under physical abuse, usually present/visible due to the aforementioned age-related changes and susceptibility of the tissues, and bite wounds. Injuries from the penis within the victim's mouth include laceration of the frenulum and palatal petechiae.

A sexual assault examination should be performed including swabs and smears from the mouth, cervicovaginal, and anorectal areas. A saline mount can be performed to look for motile spermatozoa. Smears can be Papanicolaou-stained. Swabs should be air-dried and submitted for semen and DNA analysis. A purple-top vacutainer (with ethylenediaminetetraacetic acid (EDTA)) of blood is taken as a control DNA specimen. Photographs should be made and positive and negative findings documented. Clothing and bedding should be collected.

Mimickers of sexual abuse must be excluded. Lichen sclerosis to the vulva, which is friable and bleeds easily, can be mistaken for abuse. The uterus or bladder can prolapse and become irritated secondary to friction and malposition, resulting in erythema and friability of the external aspect of these structures. The vagina can display excoriations due to postmenopausal atrophy. The vagina has an increased pH and is prone to vaginitis. Chemotherapy can also cause vaginal atrophy and dryness with decreased estrogen. Perineal dermatitis and penile excoriation secondary to urinary and fecal incontinence or poor hygiene can be very worrisome for abuse. With age, the anal sphincter tone is decreased giving the appearance of dilatation secondary to sodomy. Postmortem anal dilatation and postmortem scrotal drying artifacts may also be mistaken for sexual abuse. The elder may be constipated secondary to medication or organic changes resulting in anal fissures.

Hemorrhoids and inflammatory bowel disease can present with findings of bleeding, swelling, and tissue friability. Easy bruisability of the vulva and perineal structures secondary to coagulopathies including alcoholism can mimic blunt force trauma. Contact dermatitis and fixed drug reactions can also appear on the penis, vagina, and buttocks and simulate abuse.

Mimickers of elder sexual abuse

Vaginal lichen sclerosis
 Vaginitis with increased pH
 Vaginal bleeding due to decreased estrogen
 Coagulopathies with easy bruisability
 Constipation, anal fissures, hemorrhoids
 Perineal excoriation due to incontinence
 Perineal excoriation due to poor hygiene
 Inflammatory bowel disease
 Decreased anal sphincter tone
 Postmortem anal dilatation, postmortem scrotal drying
 Cystocele
 Fixed drug reaction
 Contact dermatitis

Physical findings suspicious for elder abuse

Fractures

- Facial bones, skull
- Long bone shaft
- Untreated/lack of medical intervention

Contusions

- Inner arms and legs
- Axillae
- Palms and soles
- Face, eye, ear/mastoid
- Scalp
- Intraoral
- Anogenital
- Buttocks
- Varying ages, different body planes

Abrasions, ulcers

- Untreated decubitus ulcer, especially grades 3 and 4
 - Wrists and ankles (restraints, ligature)
 - Intraoral (gingival, frenulum, palate)
 - Anogenital
-

Institutions

Although most elder abuse occurs outside of institutions, this setting remains one of concern for families and the elders themselves. Within an institution, any of the aforementioned types of abuse may occur. The elder resident of an institution is usually vulnerable, mentally and/or physically frail, and isolated. In too many cases, the family rarely visits, adding to the isolation of the elder. The perpetrator in cases of institutional abuse may be a resident or a visitor, but is usually a worker. The typical worker perpetrator is young, less educated, and in an institution with a high employee turnover. The isolation and

inability of the elder victim to report the abuse prevents discovery as does the fact that very few institutionalized elder deaths are investigated. In one study, <1% of these deaths were autopsied.

Autopsy

All deaths of suspected elder abuse should be autopsied. A scene investigation may be indicated depending on the case. The autopsy should be complete beginning with review of the medical records. The complete medical record may be quite extensive, but a summary of the past medical history as well as any recent hospitalization or daily institution records should be reviewed. This should include dietary records, medication and/or pharmacy records, and any therapy records indicating the abilities or disabilities of the elder. At autopsy, full body radiographs should be obtained to detect any acute or healing fractures, demineralization, or osteomyelitis from decubitus ulcers. Photographic documentation of positive findings and pertinent negatives is very important. The absence of decubitus ulcers in a thin, bed-ridden elder is just as important to document as a traumatic injury (Figure 5).

The various pathology laboratories should be utilized for ancillary studies such as microbiology cultures of blood/lung/decubitus ulcers, vitreous chemistry for electrolytes/glucose/ketones, toxicology of urine and peripheral blood, cytology with Papanicolaou staining of sexual assault examination smears, DNA and semen analysis of sexual assault examination specimens, and histology of organs and tissues including bone and ulcer sites. At the conclusion of the autopsy, a posterior 'Y'-incision and cut-downs of the extremities and buttocks should be performed to thoroughly evaluate any obvious or occult blunt force trauma.

Autopsy of the elder abuse victim

Before the autopsy

- Scene investigation, when applicable
- Review of the medical records
- Review of dietary and pharmaceutical records
- Review of therapy records (e.g., occupational, physical)

Autopsy

Figure 5 Decubitus ulcers over pressure points and bony prominences.

- Complete autopsy
- Full body radiographs
- Photographic documentation
- Microbiology cultures of blood, lung, lesions, exudates
- Vitreous chemistry: electrolytes, glucose, ketones
- Toxicology for prescription drugs and drugs of abuse
- Sexual assault examination, when indicated
- Histology of organs and tissues
- Histology of any lesions (e.g., decubitus ulcer, lytic bone)
- Posterior 'Y'-incision
- Anterior and posterior cut-downs of extremities and buttocks

Although most elders aged 60 years and older will suffer from and die of their natural diseases, elder abuse is prominent and now increasingly recognized as the cause of many deaths. The actual incidence of elder abuse will only be discovered if we become better investigators in the health and lifestyles of these individuals. The elders comprise a unique group of individuals with a different physiology, with different pathologies, who are frequently vulnerable, and are too often victims of abuse.

Torture

H Vogel, University Hospital Eppendorf, Hamburg, Germany

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The definition of torture varies depending on the source of the definition and the political or social agenda of the organization that created the definition. Encyclopedias, governments, international organizations, and nongovernment organizations (NGOs) commonly have different definitions for torture: for instance, the *Encyclopedia Britannica*, Wikipedia, the World Medical Association, Amnesty International (AI), and state governments may have strikingly different definitions of torture. In spite of the differences between these definitions, however, the existence of torture, and its coexistence with and dependence on violence are generally accepted facts. Torture is particularly dangerous because it is difficult to control: the application of physical or psychological violence for the purpose of torture often creates a dynamic of its own, causing the procedure to gain its own momentum and separating the torture from the original intent. In other words, the torture will be committed for its own sake, rather than for the sake of eliciting information. Furthermore, torture is typically inflicted by, at the instigation of, or with the consent or acquiescence of, a public official or other person in authority. Therefore, perpetrators of torture are often attached to government bodies or to others who exercise power, such as organized criminal groups or insurgents. The association of torture with persons of authority may decrease the likelihood that the victims receive appropriate medical care in the aftermath of the torture, particularly in the acute phase. Because torture often requires the services of health professionals and legal professionals, it raises (additional?) ethical conflicts.

Because intelligence is required to win wars, and torture is sometimes viewed as an acceptable and expeditious method for eliciting intelligence; torture may be practised by governments and opposition groups, such as terrorist and insurgent groups, in times of war. Governments may also use torture to obtain information about planned or committed crimes; for example, in an attempt to prevent a terrorist attack. Government officials may argue that torture is justified when:

- Regulated by law
- The laws governing torture have been established by democratically elected officials
- The laws governing torture are applied by democratically elected governments

Waterboarding is a recent example of government use of a practise that is widely believed to be a torture technique. Waterboarding was considered acceptable and used by the administration of US President George W. Bush for the purpose of interrogating suspected al-Qa'ida members following the 9/11 attacks. Use of waterboarding has been condemned by many NGOs, including AI.

Torture is an age-old activity that has become more sophisticated with the passage of time. It is usually carried out

clandestinely, and there is often a deliberate attempt to reduce any physical evidence of its practice. Therefore, documentation of such abuse is usually difficult to find; in the absence of physical evidence at the time of examination, accounts of torture are often based solely on historical reports. Typically, most torture is carried out in the early stages of the victims' confinement. If the torture is not initially fatal, the physical signs of torture have typically healed by the time the victim is released.

Victims who survive torture have usually been less severely tortured than those who died. Victims who have escaped from torture and come to the attention of rehabilitation centers in Europe, America, and elsewhere are presumably less severely tortured than those victims who were unable to escape. Torture that results in mutilation increases the probability that the victim will die. Victims who have been stabbed in the trunk (wounds that are oftentimes followed by pleurisy and peritonitis) survive less often than those who have been wounded only in their extremities.

Documentation of torture employs similar procedures, techniques, and modalities as are employed in the investigation of other forms of abuse. These procedures, and the equipment necessary to properly implement them, are usually scarce in countries where torture is common. This is the case in times of peace or war.

These circumstances influence any description of torture and the possibilities as well as opportunities to prove that torture has occurred.

Forms

The majority of torture methods have been in practice for many years. It is common for aggressors to invent new names for old procedures in order to make the torture technique seem less harmful, so that the technique is more acceptable to the public. Variations on existing methods and new methods have been developed in order to make it impossible to prove torture through physical examinations.

If physical findings of torture are present, the differential diagnosis must include other forms of physical damage, such as that caused by:

- abuse/maltreatment
- accidents, self-inflicted injuries
- initiation rites
- diseases

Torture methods may be used on all parts of the body, including the hand and arm, foot and leg, trunk (including genital organs), and head and neck. Special torture procedures are used on fingers, hands, and arms. Torture procedures include:

- Postural torture
- Stabbing and cutting of any part of the body
- Finger, hand, and arm

Figure 1 (a–c) Metallic foreign body left in soft tissues of the middle phalanx of the second and third fingers. During torture, needles or wires were introduced underneath the fingernails. Splinters remained after they were withdrawn.

- Toe, foot, and leg
- Compression injuries
- Petite guillotine
- Water torture
 - Submersion
 - Deprivation
 - Forced ingestion
- Electric torture
- Psychological torture methods
- Noise, music, light, cold, etc.

Combinations of the techniques listed above are frequent.

Fingers

Torture involving the fingers is quite common and may produce reversible or permanent anatomical alterations. The effects of a variety of techniques can be seen in rehabilitation centers for torture victims.

Foreign bodies: When fingers are injured with needles or other sharp instruments, foreign bodies (pieces of those instruments) may become permanently lodged in the fingers. The introduction of needles, wires, or wooden splinters beneath the fingernails is widespread. These foreign bodies are often directed to the distal interphalangeal joint or even beyond. When retracted, splinters or other fragments may remain and be radiographically detectable (**Figure 1(a)–1(c)**).

Fingernails: In South America and elsewhere, the extraction of fingernails has been practised; this procedure, however, has reversible effects.

Loss of fingers and toes: Compression of digits by finger, thumb, and toe screws has been applied since medieval times. Bone damage may be minor (**Figure 3**) or major and lead to complete loss of a phalanx. Less severe mechanical compression injuries are inflicted by stomping or striking with rifle butts or other objects. Fingers can also be lost (**Figure 2(a)** and **2(b)**) or severely damaged by direct violence or by neurovascular loss as a result of squeezing. Squeezing can be accomplished by placing a stick between the fingers and

Figure 2 (a and b) Finger loss due to squeezing.

Figure 3 The guards of the Islamic Revolution imprisoned this 14-year-old girl. Parts of her fingers were cut off in the prison with the petite guillotine.

then compressing them against each other in order to damage nerves and vessels without leaving visible traces.

Petite Guillotine: Using this device, the fingers, or parts of fingers, can be cut off in succession (Figure 3). The Petite Guillotine was developed in Iran during the times of the Shah and persists to present times.

Suspension: Suspension on one or several fingers is reported from the Kurdish territories in the Arabic peninsula and in the neighboring countries. Suspension on fingers is an old method that has been in use since medieval times, for example, as punishment on sailing ships. It induces necrosis and loss of the finger. The thumb seems to be the preferred finger, perhaps for anatomical reasons (Figure 4(a) and 4(b)) and because of its major functional importance.

Hands and Arms

Amputation: During the civil war in Sierra Leone, the hands of possible voters were cut off to prevent them from voting, as painting the fingers of individuals after they had voted controlled the national vote. Cutting off hands and feet of perpetrators of certain crimes is prescribed by Shari-ah, the law of the Koran. This punishment is applied in several Islamic countries where the Shari-ah is the official law.

Defensive fractures: The fracture of the forearm is a typical injury of defense. Persons instinctively or intentionally try to protect their head when under attack. A nightstick may fracture the ulna alone or the ulna together with the radius (Figure 5).

Mutilation: In Zaire, fractures of the hands and wrists are seen in journalists, writers, and artists (Figure 6). The aim is not only to hamper the victim's work, but also to cause functional injury by mutilating the part of the body that is the victim's main instrument of livelihood.

Fire: Scars from serious burns can cause contractures and deformation. Torture by fire has been reported in Africa.

Postural torture: This can be accomplished by requiring the victim to maintain a certain awkward (and even physiologic)

posture for long periods of time, by binding the victim in various awkward and painful positions, or by suspension of the victim. Victims are sometimes suspended by the arms, which are bent backward with upward traction applied. Other forms bind the hands and feet together at the back (Figure 7).

Figure 5 Fresh fracture (fending fracture) of the ulna. Defensive injuries sustained during beating.

Figure 4 (a and b) Loss of thumb due to suspension (Kurd). This image from a hospital in Berlin shows how the fifth finger replaces the lost thumb.

Figure 6 Crushed wrist of a journalist (Zaire).

Often, postural torture is applied with the intention to avoid evidence of the abuse. Figure 8 depicts common forms of postural torture and suspension from South America.

Having been imprisoned in a cage less high than the prisoner's height is reported from Kurds, Chinese, and Chileans. 'Uncomfortable' positions can be easily enforced. Torture methods used in the 'Abu Ghreib' prison in Iraq forced prisoners to maintain similar or identical positions, according to photographic evidence.

Foot and Leg

Feet and legs are common targets of torture; some techniques are fairly specific to geographic regions. Imaging may show

Figure 7 Dislocation of the glenohumeral joint: glenoid process of scapula, humeral head, Hill–Sachs lesion in proximal humerus. Suspension by the elbows, the arms bent backward. With such a suspension, dislocation of the shoulders is less common.

typical or even characteristic findings; examples are falaka and palmatoria.

Falaka: Falaka is a widespread form of torture, sometimes known as falanga and in Spanish-speaking areas as bastinado. Falaka means beating the foot, primarily (but not exclusively) on the sole of the foot. Falaka is perpetrated in the Middle East (especially in Turkey and Iraq), in the Far East, and in some Spanish-speaking areas. Falaka produces edema, hematoma, fractures and injuries to the ligaments, tendons, fascia, and aponeurosis of the feet and ankle (Figure 9(a)–9(d)). Shortly after torture, the clinical findings alone are usually diagnostic. Radiography can confirm or exclude fractures and allow estimation of the time interval since torture was applied.

In the author's experience, these beatings may fracture the toes, the metatarsals, the tarsals (especially the calcaneus), and occasionally the ankle. This is especially the case if the feet were fixed during the beating. Fractures of the lateral malleolus seem to be an exception; nevertheless, the lower leg near the ankle may be involved. Scintigraphy initially shows increased soft tissue activity after the beating (Figure 9(d)). Later, a generalized increased bony uptake with unusual degenerative changes may be found. When available, magnetic resonance imaging (MRI) is better than computed tomography (CT) in visualizing alterations of soft tissues including capsular thickening, atrophy, edema, and reparative changes. Later studies may prove earlier torture by demonstrating a thickened aponeurosis of the foot. MRI can also show bone bruises or edema.

Palmatoria: Palmatoria is an example of a method of localized torture that is virtually unique to a specific region – the small West African country of Guinea-Bissau. Palmatoria involves repetitive blows to the shin where the tibia lies closest to the skin. Radiographic examination may show periosteal reaction from subperiosteal hemorrhage and hematoma. Laminar or onionskin periostitis can persist for weeks or even years. Somewhat peculiar endosteal and medullary changes may be seen as well. Two case reports have shown that blows to this area of the tibia, using a rod, can produce a hidden endosteal fracture, which is likely to be undetected on plain films but obvious on CT. It is possible, and perhaps even likely, that

Figure 8 Common forms of postural torture, which hardly leave evidence, could be demonstrated by diagnostic imaging: 'Il moto' (middle) and 'la barra' on the right.

Figure 9 (a) Falaka. (b) Photograph of a foot after falaka. (c) CT, top: edema and hematoma, predominately plantar after falaka; below: chronic change after falaka, splay and flatfoot deformation due to relaxed ligaments and aponeurosis. (d) Scintigraphy: very high uptake in feet, several weeks after falaka.

some of the African cases would show similar findings, had more sophisticated imaging modality been applied.

Compression: Compression of digits by toe screws has been applied in Iran (Figure 10(a) and 10(b)). Bony damage can be of various degrees, and complete loss of a phalanx or an entire digit may occur. Mutilation is a possible consequence.

Foreign bodies: Corresponding to torture methods used on fingers and hands, foreign bodies are also introduced into the toes, often under the toenails (Figure 18) and into the feet. Radiography might find remaining splinters.

Toenails: Like fingernails, toenails may be extracted.

Extreme cold: Exposure to low temperatures may result in frostbite or even frozen-off toes.

Kneecapping: Kneecapping is a term originally used to describe a gunshot wound in the knee, usually by a handgun, in order to permanently maim or cripple the victim. In America, it has been mostly associated with gang warfare. In recent years, it has been seen during the civil strife in Northern Ireland. It is not certain as to which country is the importer and which the exporter. Kneecapping is no longer limited to the knee; other joints, particularly the ankle and elbow, are also targeted. In one known extreme case, both knees, both ankles, and both elbows were shot. Occasionally, other parts of the leg are involved. Radiographs can easily document the extent of injury and frequently disclose the bullet path, trajectory of fire, and

location of the bullet. Bullets are frequently found in situ, as low-velocity weapons are often employed. Arterial damage is not uncommon, and angiography is frequently employed (Figure 11(a)–11d)).

Fire: Another famous incident of torture happened to Cuauhtémoc, the last king of the Aztecs, whose feet were burnt to mutilation on 15 October 1521 by Hernán Cortés.

Head

Torture applied to the head is often fatal, a consequence that is usually accepted or even intended by the torturers when they use such techniques.

Stabbing: Only a few cases of this typically lethal wound have been documented (Figure 12(a) and 12(b)).

Beating: Beating the head may fracture the bones and cause intracranial bleeding. Teeth are often broken or dislocated during beating. These may be extracted or drilled as a form of pain induction. These injuries, of course, can be demonstrated by direct inspection as well as by radiography. In Chad, an uncommon form of torture involves a prisoner being beaten in the face producing fractures of the facial bones that can be demonstrated radiologically. Opacification of the maxillary sinuses is regularly seen due to bleeding, and subsequently sinusitis may develop.

Figure 10 Destroyed toes after screw compression (Iran). Photograph and radiograph.

Shaking: In the Middle East, the technique of violently shaking the suspect's upper torso is used. Occasionally, this may produce intracranial lesions much like those in the shaken baby syndrome. In Israel, the Supreme Court has outlawed this practise.

Neck

Strangulation: Strangulation as a special form of suffocation is employed worldwide, either for tormenting or for outright killing. Fracture of the larynx may be seen. Some European states have employed strangulation as one form of capital punishment. In Spain, the Garrote was used for executions under Franco.

Trunk

Beating: Few specific injuries will be detected from generalized beating because, as pointed out, soft tissue and bony injury usually heal by the time the victim comes to sympathetic medical attention. Residual deformities of rib and spinal fractures may be present, as may be deformities due to ligamentous tears or ruptures. Scintigraphy (Figure 13) shows increased bone metabolism up to 2 years after the beating, and may indicate a pattern of the beating.

Stabbing: Stabbing in the trunk carries a high risk of injury to vital organs, with a consequent high probability of a lethal infection. Therefore, this method is less seen and reported. In South Africa, gangs have been hunting young women to torture them by introducing bicycle spokes into the umbilicus. A variant of this was stabbing into the spine with intent to

produce paraplegia. When stabbing occurs, fragments of the weapon or foreign bodies may remain and can be documented by a radiological method (Figure 14).

Injection: In former East Germany, a young man on his way to a discotheque was attacked by a gang and rendered unconscious. Upon being brought to the hospital, it was discovered that mercury had been injected into his chest wall.

Fractures: Rib fractures are common. Scintigraphically, they may be especially helpful to show the pattern of beating. Less known is the fracture due to compressing of chest or the pelvis.

Anus and genitals: Violence is often directed at genital organs (Figure 15). Hours after the abuse, scintigraphy may show an increased activity at the site of the injury. Diagnostic imaging can document some of the consequences, for example, remaining foreign bodies after sexual torture. Some injuries associated with perforation will often provoke death before diagnostic imaging is done. Stabbing into the anus is sometimes performed to make the victim suffer before death and/or to hide the killing from the public.

Sexual abuse of women, including female circumcision, is well known; however, violation of men is reported less often. A famous case is that of Mugabe, current president of Zimbabwe, who was violated in his youth. In Abu Ghraib, male prisoners were forced to perform sex acts on each other.

Electric Torture

Electricity as an instrument of torture can be used in multiple ways. In the Middle East, it is common to place the electrode between the toes, on the tongue, on the teeth, or on the penis. The location between the toes and on the tongue is chosen in order to hide the place of entrance of the electric current.

Figure 11 (a–d) Kneecapping, employing weapons. Shot into the upper leg with lead shot. Shot into the knee with a handgun. The projectile remains in the knee.

The placement on the penis is selected not only to inflict pain but also to humiliate. In Africa, electrodes are placed on the teeth. In the Middle East, large electrodes are used on wet skin, and collar-like electrodes are placed on the neck. Electric current induces muscle contractions, which may result in outright bone fractures and/or soft tissue injuries, with subsequent later

degenerative bone or joint changes. Electroshock may produce compression fractures of the vertebrae. Grand mal seizures may cause high thoracic vertebral fractures. Moreover, teeth can be lost and jaws broken.

For proving electric torture, local incision and microscopic evaluation may show characteristic necrosis, which is accepted

Figure 12 The original comment was 'nail in head, witchcraft, deceased.' The victim was said to be possessed by an evil spirit; the healer chose to liberate his patient from this evil by putting a nail into his head. The victim died after some days in hospital. Today, the author thinks this was a 'medical killing' ('ritual murder') scheme, and that the killing was part of a magic procedure (Africa).

Figure 13 Beating. Scintigraphy. Increased bone metabolism in the anterior part of a rib on the right side of the victim due to beating.

Figure 14 Needle fragments in the chest after stabbing with multiple needles.

as evidence by judges in Turkey. If the victims were immediately available, torture by electricity could probably be confirmed by MRI, such as the findings of high signal alterations on MRI examination of the chest in (normal, not tortured) patients undergoing cardioversion have indicated.

Water submersion: In submersion, often called 'submarine,' the victim's head is forced underwater until near drowning. The water is often polluted with excrement. Aspiration is

Figure 15 Scintigraphy to document squeezing injury to the right testis. Dynamic scan.

virtually inevitable and the subsequent radiography changes may vary from pulmonary edema to extensive pneumonia. The latter may result in residual pulmonary scarring and adhesions. The findings are nonspecific, however.

Water deprivation: Deprivation of water can be an effective, even deadly, form of torture.

Water ingestion: Victims from Chad, Africa, have reported that they were bound with their arms behind them, then forced to ingest several litres of water within a very short time. Thereafter, they were thrown, or caused to fall, from a height of several meters to land on their anterior chest and abdomen, with the aim of visceral rupture. One survivor was found to have a diaphragmatic hernia that might have been induced by this forced trauma.

Waterboarding: In this technique, a cloth or plastic wrap is placed over or in the person's mouth, and water is poured on to the person's head. In 2005, waterboarding was characterized as a 'professional interrogation technique' by former CIA director Porter J. Goss; however, CIA officers who have subjected themselves to the technique lasted an average of 14 s before capitulating. There is a real risk of death from drowning, suffering a heart attack, or damage to the lungs from inhalation of water. Long-term effects include panic attacks, depression, and posttraumatic stress disorder.

Psychological Torture

Execution/Russian roulette/pretended execution: Victims of torture may be forced to assist in the execution and the torture of others. Not only do they see what they have to expect when it is their turn to be tortured, but they are often compelled to torture or kill a companion, friend, or relative. They may also be subjected to their own fake execution or forced to engage in Russian roulette.

Music/noise: Music may also be used for psychological torture. In nearly every German concentration camp, the SS forced victims to join orchestras that played military marches, folk songs,

and popular songs, making the musicians feel as though they had joined forces with the SS; many of them committed suicide. Being exposed to loud or offensive music can break the victim's personality and give torturers absolute control.

Diagnosis and Differential Diagnosis

Torture can be classified as somatic, (bio)chemical (pharmacological), and psychological. However, multiple forms of somatic torture are designed and applied in a manner so as to avoid distinctive evidence by subsequent visual or radiologic inspection. Some techniques produce changes that can be depicted by imaging. In general, psychological and pharmacological torture does not lend itself to radiologic discovery; it seems possible, however, that, in the near future, functional MRI will be able to evidence findings which are characteristic for pharmacological torture and, in consequence will allow proving it. Diffusion tensor imaging (DTI) offers a promising approach: DTI can show damages of axons which are not visible on conventional MRI.

Physical and psychological examination is the basis of the investigation, and diagnostic imaging may contribute in certain cases. The findings have to be combined with the person's history and the cultural background of the case. There are regional differences in the design and infliction of torture and mistreatment throughout the world, and, unfortunately, new forms of torture are constantly being invented. The plausibility of the individual's history – specifically, the pattern of the inflicted physical and psychological violence – should be examined. These data are to be compared with what is known about the region, the time, and the forces/organizations which are said to have been involved in the torture. Diagnostic imaging sometimes allow visualizing a pattern and gives an approximation of the time passed. It is recommended to consider other causes of presumed torture trauma, such as accidents, crimes, local customs, and initiation rites, all of

which may produce the same effects. Self-flagellation practiced by Shiites during the Ashura festival may serve as example: young men beat themselves on the back with multiple blades, resulting in bleeding, and the healing produces scars that should not be attributed to beating inflicted by others.

Ethics

Most medical organizations state that participating in torture is against medical ethics. However, physicians and other medical professions have been called upon to assist and/or supervise torture, provide expertise in rendering torture methods more effective, help in covering up consequences of torture, or modify (falsify) a forensic certificate. A conflict is also apparent when a physician is called upon to provide medical care for a person who has been tortured, remains in custody, and will be tortured again. Leopara and Millum, both activists with Médecins sans Frontières, discuss this problem and conclude: "If a tortured patient demands medical care, the physician should accept some form and degree of complicity in torture in order to assist the tortured patient. Three main factors should guide a doctor's decision in such circumstances: the expected consequences of the doctor's actions, the wishes of the patient, and the extent of the doctor's complicity with wrongdoing."

Conclusion

While objectivity is required, one must also constantly bear in mind that the case is not merely theoretical, but actually concerns a real human being. Much of the evidence comes from worldwide centers of rehabilitation for torture victims. Imaging sometimes depicts lesions so characteristic that they can be considered legal proof of previous torture and verify a presumed victim's claims.

Criteria that support claims of torture are:

- Correlation between the type of torture and the findings derived from imaging procedures
- Correlation between the date of torture and the imaging appearance of the lesion
- Specific alterations, such as the periosteal reactions from palmatoria
- Correlating findings in a particular situation, such as imprisonment and nutritional deficiencies or sequelae from denial of treatment or surgery
- Patterns of beatings (proven by imaging) typical for a particular geographic location and corresponding with the victim's story

Forensic Age Estimation

A Schmeling, Institute of Legal Medicine, Münster, Germany

Introduction

Despite the alleged use of the eruption of second molars by the ancient Romans to evaluate readiness for military service, age diagnostics in living individuals is a relatively young branch of applied research within the forensic sciences. However, in recent years, its value and importance as an assessment tool has risen exponentially as the requirements for an informed opinion on the age of an individual have assumed increasing importance for the assessment of both legal and social categorization.

There are many areas in which the evaluation of age in the living have gained significant importance in recent years but the most prevalent concern issues pertaining to refugee and asylum seekers, suspects and delinquents, human trafficking, and child pornography. Age evaluation is also required for adoptive children from countries without birth registration. A further category which is on the rise is age evaluation in competitive sports to ensure that athletes are competing within an age-appropriate banding both for the sake of fairness and health protection. Parents have also been known to falsify the ages of their children, particularly of their sons, to obtain preferential educational opportunities. While it is undeniable that the majority of issues raised concerning age evaluation are predominantly within the juvenile aspect of the human age range, there are issues of legality in relation to the elderly, which tend to relate to matters of eligibility for state pension support or retirement law.

The first transregional scientific analysis of forensic age diagnostics in living individuals was conducted on the occasion of the 10th Lübeck Meeting of German Forensic Physicians in December 1999. At this meeting, it was suggested that a study group be set up, which would include forensic pathologists, dentists, radiologists, and anthropologists. They were tasked with producing recommendations for the issuing of expert opinions in order to standardize the hitherto common and partly varying procedure and to achieve quality assurance for expert opinions.

The international and interdisciplinary 'Study Group on Forensic Age Diagnostics' was established in Berlin, Germany, on March 10, 2000. This study group has given recommendations for forensic age estimation in living individuals in criminal proceedings, in civil and asylum procedures, as well as in pension procedures. As an external quality control measure, the Study Group on Forensic Age Diagnostics annually organizes proficiency tests in which participants are sent the X-rays and physical examination results for a set of subjects and asked to estimate their ages.

Because of the explosive growth in knowledge over recent years, only qualified specialists in the field of forensic age diagnostics are capable of supplying expert opinions based on the current state of the sciences. A member list of the Study Group on Forensic Age Diagnostics can be downloaded from the Study Group's homepage. Successful participants in

the Study Group's proficiency tests are also published on this homepage.

Outlined below are the methodological principles of forensic age diagnostics as applied to adolescents and young adults, child victims in child pornographic picture documents as well as to older adults for the purposes of clarifying pension entitlements.

Age Estimation in Adolescents and Young Adults

General Remarks

The persons to whom forensic examination is to be applied are foreigners without valid identity documents who are suspected of making false statements about their age and whose genuine age needs to be ascertained in the course of criminal, civil, or asylum proceedings. In many countries, the legally relevant age thresholds lie between 14 and 22 years of age.

According to the recommendations of the Study Group on Forensic Age Diagnostics for an age estimate, the following examinations should be performed in combination:

- Physical examination with determination of anthropometric measures (body height and weight, constitutional type), inspection of signs of sexual maturation, as well as identification of any age-relevant developmental disorders
- X-ray examination of the left hand
- Dental examination with determination of the dental status and X-ray examination of the dentition
- If the skeletal development of the hand is complete, an additional examination of the clavicles should be carried out, preferably by means of a conventional X-ray examination and/or a CT scan.

Guidelines for the use of ionizing radiation vary from country to country. When utilizing X-rays, the local regulations, statutes, or professional guidelines should be observed. As X-ray examinations for forensic age diagnostics take place without medical indications, the question should first be pursued as to whether the effective radiation doses given during the procedures used could be detrimental to the health of the persons examined.

Radiation Exposure in X-Ray Examinations for the Purpose of Age Estimation

The effective dose from an X-ray examination of the hand is 0.1 microsievert (μSv), from an orthopantomogram (OPG) 26 μSv , from a conventional X-ray examination of the clavicles 220 μSv , and from a CT scan of the clavicles 600 μSv . According to the relatively high effective dose of the X-ray and CT examinations of the clavicles, their use should be restricted to individuals with completed hand ossification.

In order to assess the potential health risk of these X-ray examinations, the amounts of naturally occurring and civilizing

radiation exposure are compared to amounts of radiation exposure from radiological procedures. The effective dose from naturally occurring radiation exposure in Germany is 2.1 mSv (millisievert) on average per year. Apart from the direct cosmic radiation of 0.3 mSv and the direct terrestrial radiation of 0.4 mSv, the ingestion of naturally occurring radioactive substances in the food contributes 0.3 mSv to the radiation exposure. For the inhalation of radon and its disintegration products, 1.1 mSv must be added. Compared to naturally occurring radiation exposure, one hand X-ray equals the naturally occurring radiation exposure of 25 min, one OPG is equivalent to 4.5 days, one X-ray of the clavicles is equal to 38 days, and one CT of the clavicles equals 104 days.

The radiation exposure from an intercontinental flight at an altitude of 12 000 m is 0.008 mSv per hour. It follows that the dose for a flight from Frankfurt to New York is 0.05 mSv. This means that the radiation exposure from two orthopantomograms is equivalent to the radiation exposure from an intercontinental flight.

On the basis of this comparison, a relevant health risk as a result of X-ray examinations for forensic age estimations can be denied.

Concerning a possible health risk, the biological effect of X-rays needs to be discussed as well. In this case, a distinction between stochastic and nonstochastic radiation effects has to be made. Nonstochastic effects appear above 100 mSv and are therefore irrelevant to radiological diagnostics. DNA damage leading to mutations of the genotype and malign diseases is one of the stochastic effects. On the assumption that there is a linear dose–effect relation without a threshold between the risk of radiation exposure and the delivered radiation dose and thus that even X-rays in the low-dose region can cause a malign disease, cancer mortality risks can be calculated for adults and children. It has to be pointed out that the risk for children is twice the risk of adults. The German radiation biologist Jung compared the mortality risk of X-ray examinations for age estimations with the mortality risk resulting from the participation in traffic. He came to the conclusion that the mortality risk of an orthopantomogram is comparable to the participation in traffic for 2.5 h. Thus the radiation risk of the X-ray examinations is as high as the risk the examined individual is exposed to on the way to the examination or the trial date. If the risk of an appointment for an age estimation seemed acceptable, this should also apply to the radiation risk of the X-ray examination.

It can be concluded that compared to other life risks, a relevant health risk of X-rays for the purpose of age estimation can be denied as well.

However, as long as the discussion about the biological radiation effect in the low-dose region is undecided, the so-called minimizing order remains valid without restrictions. It demands that any necessary examination is carried out with the minimum amount of radiation and without unnecessary exposure. Thus, no X-rays should be made beyond the examination range specified in scientific recommendations.

Physical Examination

The physical examination includes anthropometric measures such as body height, weight, and constitutional type, as well as

visible signs of sexual maturity. In boys these are penile and testicular development, pubic hair, axillary hair, beard growth, and laryngeal prominence; in girls these are breast development, pubic hair, axillary hair, and shape of the hip.

Tanner's staging for sexual maturation is commonly used to determine the status of genital development, breast development, and pubic hair growth. Axillary hair growth, beard growth, and laryngeal development may be assessed using the four-stage classification of Neyzi et al.

Of the forensic methods recommended for age estimation, evaluating sexual maturity shows the largest range of variation and therefore should be used for age diagnostics only in conjunction with an evaluation of skeletal maturity and tooth development. However, the physical examination is indispensable to rule out any visible signs of age-related illness and to cross-check whether skeletal age and tooth age correspond to overall physical development.

Most diseases delay development and are thus conducive to underestimation of age. Such underestimation of age would not disadvantage the person concerned in terms of criminal prosecution. By contrast, overestimating age due to a disease that accelerates development should be avoided at all costs. Such diseases occur very rarely and include, above all, endocrinal disorders, which may affect not only the attainment of height and sexual development, but also skeletal development. Endocrinal diseases that may accelerate skeletal development include precocious puberty, adrenogenital syndrome, and hyperthyroidism.

The physical examination should look for symptoms of hormonal acceleration of development, such as gigantism, acromegaly, microplasia, virilization of girls, dissociated virilism of boys, goiter, or exophthalmos. If no abnormality is detected, it may be assumed that the probability of such a disease occurring is well below one per thousand. Another indication for a possible hormonal disease is a discrepancy between skeletal age and dental age, as dental development normally remains unaffected by endocrinal disorders.

X-Ray Examination of the Hand

Within the area of forensic age estimations in adolescents, skeletal maturation is a vital diagnostic pillar. In this connection, the hand skeleton is particularly suitable until the developmental processes are completed at the age of about 17–18 years. The maturity status of the hand may be considered to be representative for the entire skeletal system.

As agreed, an X-ray of the left hand is taken as, in all populations, the number of right-handers is higher, and, as a result, the right hand is more often exposed to traumata which can impair the skeletal development. However, there are no reported significant differences in the ossification rate of right and left hands.

Criteria for evaluating hand radiographs include the form and size of bone elements and the degree of epiphyseal ossification. To this effect, either a given X-ray image is compared with standard images of the relevant age and sex (radiographic atlas), or the degree of maturity or bone age is determined for selected bones (single bone method).

Various studies have demonstrated that although the single bone method requires more time, it does not necessarily yield

more accurate results. Therefore, the two atlas methods developed by Greulich and Pyle as well as by Thiemann et al. seem to be appropriate for forensic age diagnostics.

Dental Examination

The main criteria for dental age estimation in adolescents and young adults are eruption and mineralization of the third molars.

Tooth eruption is a parameter of developmental morphology which, unlike tooth mineralization, can be determined in two ways: by clinical examination and/or by evaluation of dental X-rays. While 'eruption' incorporates the entire journey of the tooth from its formation in the alveolar crypts to full occlusion, 'emergence' is restricted to the time when any part of the tooth finally clears the gingival margin and becomes visible in the mouth until the stage when the tooth finally comes into occlusion with its partner tooth from the opposing jaw. Olze et al. defined a stage classification of third molar eruption based on evidence from conventional orthopantomograms (Figure 1):

- Stage A Occlusal plane covered with alveolar bone.
- Stage B Alveolar emergence; complete resorption of alveolar bone over occlusal plane.
- Stage C Gingival emergence; penetration of gingiva by at least one dental cusp.
- Stage D Complete emergence in occlusal plane.

Various classifications have been devised for evaluating tooth mineralization. They differ with regard to the number of stages, the definition of each stage, and the presentation. To assess tooth mineralization, the classification of stages made by Demirjian et al. (Figure 2) is the most suitable as the stages are defined by changes in form, independently of speculative estimates of length:

- Stage A Cusp tips are mineralized but have not yet coalesced.
- Stage B Mineralized cusps are united so the mature coronal morphology is well defined.
- Stage C The crown is about half formed; the pulp chamber is evident and dentinal deposition is occurring.
- Stage D Crown formation is complete to the dentoenamel junction. The pulp chamber has a trapezoidal form.
- Stage E Formation of the inter-radicular bifurcation has begun. Root length is less than the crown length.
- Stage F Root length is at least as great as crown length. Roots have funnel-shaped endings.
- Stage G Root walls are parallel, but apices remain open.

Figure 1 Stages of third molar eruption.

- Stage H Apical ends of the roots are completely closed, and the periodontal membrane has a uniform width around the root.

Both the eruption and the mineralization of third molars can be complete before the conclusion of the 18th year of life. Proof of completion of the 18th year of life may be provided by complete mineralization of the roots of impacted third molars as well as the lack of radiographic visibility of the root pulp or the periodontal ligament of the third molars.

Radiological Examination of the Clavicles

If the skeletal development of the hand is completed, an additional evaluation of the ossification status of the medial epiphysis of the clavicle should be performed, because all other examined developmental systems may already have completed their growth by that age.

Radiological methods to examine the medial clavicular epiphysis in living individuals are conventional radiography (CR), computed tomography (CT), as well as new approaches using magnet resonance imaging and ultrasound sonography.

While traditional classification systems differentiate between four stages of clavicle ossification (stage 1: ossification center not ossified; stage 2: ossification center ossified, epiphyseal plate not ossified; stage 3: epiphyseal plate partly ossified; stage 4: epiphyseal plate fully ossified), Schmeling et al. divided the stage of total epiphyseal fusion into two additional stages (stage 4: epiphyseal plate fully ossified, epiphyseal scar visible; stage 5: epiphyseal plate fully ossified, epiphyseal scar no longer visible). Figure 3 shows the stages of clavicular ossification for CR and CT.

There is only one study referring to conventional radiography that meets the requirements of a reference study as stated by the Study Group on Forensic Age Diagnostics. In this study, the earliest age at which stage 3 was detected in either sex was 16 years. Stage 4 was first observed in women at 20 years and in men at 21 years. Stage 5 was first achieved by both sexes at age 26. It was concluded that plain chest radiographs can essentially provide a basis for assessing clavicular ossification. If overlap in posterior–anterior views impedes evaluation,

Figure 2 Demirjian's stages of third molar mineralization.

Figure 3 Stages of clavicular ossification (CR = conventional radiography; CT = computed tomography).

additional oblique images should be taken to facilitate age estimation.

As the potential to assess CT images is dependent on slice thickness, slice thicknesses of a maximum of 1 mm should be in the practice of age estimation.

Recently, Kellinghaus et al. published data from a thin-slice CT study. In this study, stage 3 was first achieved by male individuals at age 17 and in females at age 16. The occurrence of stage 4 was first found in both sexes at the age of 21. In either sex, the earliest observation of stage 5 was at age 26.

A further improvement of age diagnostics based on clavicular ossification was the subdivision of stages 2 and 3 by Kellinghaus et al. Stage 3c first appeared at age 19 in both sexes. If stage 3c is found, it is therefore possible to substantiate that an individual has already reached the legally important age threshold of 18 years.

Comparative examinations showed that conventional X-rays and CT scans of the same clavicle can result in different ossification stages contingent on the method used. For the purposes of age estimation, this leads to the requirement to employ modality-specific reference studies.

Summarizing Age Diagnosis

The results of the physical examination, the radiographic examination of the hand, the dental examination, and the radiographic examination of the clavicles, as the case may be, should be compiled by the expert in charge of coordinating all contributions in a summarizing age diagnosis. The summarizing age estimate should include a discussion of the age-relevant variations resulting from application of the reference studies in an individual case, such as different ethnicity, different socioeconomic status, and their potential effect on the developmental status, or diseases that may affect the development of the individual examined, including their effect on the estimated age. If possible, a quantitative assessment of any such effect should be given.

The individual's most likely age is estimated on the basis of all partial diagnoses and a critical discussion of the individual case. If independent features are examined as part of an age diagnosis that combines several methods, it may be assumed that the margin of error for the combined age diagnosis is smaller than that for each individual feature. Combining methods makes it possible to identify statistical outliers,

which should also reduce the scale of variation of the overall diagnosis to a certain nonquantifiable extent.

On the basis of the verification of age estimations carried out at the Berlin Institute of Legal Medicine (Charité), it may be assumed that the range of scatter of the summarizing age diagnosis lies at around ± 12 months. Once development of the systems of characteristics examined is complete, only minimum age can be specified.

Influence of Ethnicity on the Development Systems Examined

As no forensically applicable reference studies are, as a rule, available for the regions of origin of the persons under examination, the question arises whether there are serious differences in development in diverse ethnic groups, which would prohibit the application of relevant age standards to members of ethnic groups other than the reference population.

Extensive studies of the relevant literature has demonstrated that defined stages of ossification, tooth development, and sexual maturation in the main ethnic groups relevant to forensic age estimation will proceed in the same fixed sequence so that the relevant reference studies can, in principle, be applied to other ethnic groups.

In the relevant age group, ethnicity evidently has no appreciable influence on skeletal maturation. The rate of ossification is primarily dependent on the socioeconomic status of a population. Comparatively, low socioeconomic status leads to a delay in development and thus to an underestimation of age. The application of the relevant reference studies to members of socioeconomically less-developed populations has no detrimental consequences for those affected as far as criminal proceedings are concerned – on the contrary.

With regard to the eruption and mineralization of the third molars, it has been ascertained that black Africans display an accelerated development in comparison with Europeans; by contrast, a relative retardation can be recorded in the case of Asians. For this reason, population-specific reference studies should be used to assess development of third molars in the practice of age estimation.

Methodology in Cases Where Legitimization of X-Ray Examinations Is Lacking

For age estimations without legitimization of X-ray examinations, the Study Group on Forensic Age Diagnostics recommends a physical examination covering anthropometric measurements, signs of sexual maturation, and potential age-related developmental disorders, as well as a dental examination with dental charting.

For legal reasons, findings from a radiological examination of the teeth or the hand skeleton, or other radiological characteristics of individual maturation may only be called upon if images with verified identity and known time of origin already exist.

It is to be expected that a considerable improvement in the reliability of such age estimations will be achieved in the near future by using radiation-free imaging techniques (ultrasound and magnetic resonance imaging).

Age Diagnostics in Child Victims in Child Pornographic Image Documents

In principle, age estimations in children in image documents too are made by evaluating outwardly visible growth and development processes. An evaluation of signs of sexual maturity, odontogenesis, and general proportions of the body and the face come into question.

In the evaluation of sexual maturation, the stagings commonly used in age estimations in living persons are applied. However, because of the wide variability of sexual maturation, it is only possible in exceptional cases to determine with the necessary probability that the individual portrayed is a child in the legal sense.

An assessment of dental development is a classic method of age diagnostics in children. When evaluating pictorial material, however, the examiner is reliant on sufficiently good visibility of the front teeth and on high picture quality. However, in exceptional cases where the milk teeth are well recognizable, important information on age can be gained.

Body proportions change in a characteristic way in the course of the individual development of infants into adults. Typical shifts in proportions are the result of different speeds of growth of the different regions of the body during certain phases of development. In particular, the proportional ratios between the trunk and the extremities and/or the trunk and the head, as well as the breadth and length ratios of each of the body segments can be used in age estimation. Although the assessment of body proportions alone only yields a rough age classification, it should always be included in the overall assessment.

The development of a child's face too is characterized by certain growth principles resulting in age-related facial proportions. In general, in the course of development from an infant to an adolescent and an adult, the neurocranium, which is very prominent in childhood, recedes with increasing age compared to the viscerocranium. The face itself undergoes ongoing extension, the mandible is emphasized, and as a whole, growth in height and depth as opposed to growth in breadth predominates in development. In a current pilot study, various measurements were surveyed on standardized facial photos of 373 persons in the age groups of 6, 10, 14, and 18 years. Using discriminant analysis, it was ascertained that it was possible to classify 60.3% of cases in the correct age group. Moreover, software is at present being developed within the scope of an EU project for automated age estimation on the basis of facial morphology.

Age Diagnostics in Older Adults for Clarification of Pension Entitlements

Age diagnostics in living persons for clarification of old-age pension entitlements must be carried out almost without exception on older adults (mostly from the fourth decade of life and upward). In this age range, age estimations using morphological procedures do not, as a rule, provide adequate exactitude. However, if radiological examinations of the teeth or appropriate sections of the skeleton were carried out in childhood, adolescence, or early adulthood for medical reasons and

the relevant records are still available, these can be checked for suitability for morphological age estimation. In this process, it must be ensured that the records submitted really do come from the person in question. If the issue cannot be adequately resolved by means of this approach, biochemical age estimation on the basis of the degree of racemization of aspartic acid in the dentine can be discussed. In adulthood, determining the degree of racemization of aspartic acid in the dentine leads to significantly more accurate results than morphological methods.

To determine the degree of racemization of aspartic acid in the dentine, a tooth is necessary. The extraction of a tooth is, in principle, a bodily injury which is only justified in the event of appropriate medical indications and with the informed consent of the patient. In an identity assurance protocol to be signed by the dentist and the applicant, the identity of the applicant has to be determined as well as the fact that the tooth originated from the applicant. The examinations must be carried out in a competent laboratory with an adequate quality assurance system.

Conclusions

Forensic age diagnostics in living individuals has gained considerably in significance over recent years.

For the purposes of age estimation in adolescents and young adults, the Study Group on Forensic Age Diagnostics recommends a combination of a physical examination, an X-ray examination of the hand, a dental examination providing an orthopantomogram, as well as an additional radiological examination of the clavicles in cases where the hand skeleton is fully developed.

Where there is no legitimation for X-ray examinations, the range of methods is limited to a physical examination and dental charting. By using radiation-free imaging techniques, a significant improvement of the reliability of age estimations without legitimation of X-ray examinations may be expected.

The influence of ethnicity and socioeconomic status on the age characteristics examined must be taken into account in compiling a report.

Age estimation in child victims shown in child pornographic image documents is possible by means of assessment of signs of sexual maturity, dental development, general body proportions, and facial proportions. However, owing to wide variations in the characteristics available until now, it is only possible in individual cases to ascertain with the necessary probability that the legally relevant age limits have not been reached.

Age estimations in pension proceedings can be made on the basis of radiological records dating from childhood and adolescence insofar as identity is proven. If such records are not available, an ascertainment of the degree of racemization of aspartic acid in the dentine may be considered. The extraction of the tooth required for this method is only legitimized in the presence of a medical indication and with the informed consent of the person affected.

Glossary

Acclimatization Physiological accustomization to a new climate or new conditions, especially to a change in environmental temperature or geographic elevation.

Chilblain A painful, itching swelling with erythema on the skin, occasionally accompanied by blisters or ulcers, in the peripheries including the hands, feet, ears, and nose, caused by impaired microcirculation, as a consequence of persistent or intermittent cold exposure, usually in combination with high moisture.

Dehydration A state of body water loss sufficient to cause intravascular volume deficits, with or without loss of electrolytes.

Drug adverse effect An unintended result of therapeutic use of a drug, usually with an undesirable harmful effect.

Frostbite A severe local skin lesion caused by freezing cold, usually on the hands, feet, ears, and nose, as a consequence of stagnant blood flow and edema due to paralytic vasodilatation in combination with inflammation and necrosis.

Heat cramp Usually nonfatal, painful muscle spasms with headache, thirst, and hypotension but without hyperpyrexia, induced by exertion in a hot environment, typically related to salt deficiency.

Heat exhaustion A continuum with heatstroke, mainly resulting from hypotonic dehydration due to excessive sweating (hyperhidrotic heat exhaustion), marked by prostration, weakness, fainting, and vascular collapse, usually with nearly normal body temperature; otherwise, a thermal disorder accompanied by failure of sweating (ahidrotic heat exhaustion), possibly due to dysfunction of the sweat mechanism.

Heat shock protein A ubiquitous protein group, which is induced by various stressors, including heat and cold, and functions to reduce the harmful consequences.

Heat stroke A severe potentially fatal illness involving thermoregulatory disorder due to extremely high environmental temperature, characterized by hot and dry skin, and cerebral dysfunction involving confusion, accompanied by an elevated body temperature (often over 40 °C), resulting in vascular collapse and coma.

Heatwave A prolonged period of unusually hot weather as a climatic cause of accidental heat stroke.

Hide and die A peculiar aspect of some cases of fatal hypothermia, where the victim is found hiding away from sight, often undressing (paradoxical undressing), indicating hypothermic brain dysfunction.

Hyperpyrexia Excessive unusual elevation of core body temperature over 40.0–41.5 °C (104.0–106.7 °F), or extremely high fever, caused by various exogenous and endogenous factors, including an extremely hot environment, drugs, toxins, and fibril diseases.

Hyperthermia A pathological condition with an elevated core body temperature, usually over 40 °C (104 °F), caused by high environmental temperature, or induced by drugs or other chemicals: synonym of hyperpyrexia.

Hypothermia A pathological condition with a decreased core body temperature, usually below 35 °C (95 °F), caused by low environmental temperature (cold exposure), or induced by drugs, or artificial cooling for therapeutic purposes.

Malignant hyperthermia A rare life-threatening condition involving an extreme rise of core body temperature (hyperthermia), triggered by exposure to specific drugs used for anesthesia in patients with a genetic defect: synonym, malignant hyperpyrexia.

Malignant syndrome A potentially life-threatening neurological disorder involving an extreme rise of core body temperature (hyperthermia) and rhabdomyolysis, induced by drugs, mainly narcotics, psychotropics, and analgesics.

Multiple organ dysfunction syndrome (MODS) A clinical condition defined as the presence of altered organ function, usually involving two or more organ systems, in an acutely ill patient such that homeostasis cannot be maintained without intervention, describing the process as a continuum of physiological derangement (dysfunction) that changes over time, instead of earlier terminology such as multiple organ failure (MOF) and multisystem organ failure (MSOF).

Paradoxical undressing A peculiar aspect of some cases of fatal hypothermia, where the victim is found partly or even totally naked in a cold environment, aggravating heat loss, possibly as a consequence of hypothermic brain dysfunction.

Rhabdomyolysis Diffuse skeletal muscle injury involving myoglobinemia and myoglobinuria, caused by various factors, including injury, ischemia or hypoxia, alcohol, drugs, and other chemicals, resulting in renal dysfunction.

Serotonin syndrome A potentially life-threatening neurological disorder involving an extreme rise of core body temperature (hyperthermia) and rhabdomyolysis, as a drug adverse effect of selective serotonin reuptake inhibitor (SSRI, antidepressant).

Social deprivation Living conditions lacking adequate social care or support.

Sunstroke A form of heatstroke caused by excessive exposure to the sun's rays, presenting with hypotension, tachycardia, and cold sweat due to vascular collapse, often without hyperpyrexia.

Suspended animation A temporary state simulating death, where vital signs cannot be detected clinically.

Systemic inflammatory response syndrome (SIRS) A clinical concept that implies a systemic inflammatory process arising from a variety of severe insults, including infection and noninfectious causes. The systemic response

is termed 'sepsis' when it is the result of a confirmed infectious process.

Thermoregulation The physiological regulation of body temperature, which is maintained by a balance between heat load and loss; heat is produced in the oxidative metabolic process and acquired from the environment, and is lost by conduction, radiation, and evaporation

involving sweating and insensible heat loss (mainly, moisture loss from the skin and lungs). The thermoregulatory center is located in the preoptic anterior hypothalamus.

Wischnevsky spot Multiple dark-brownish punctate gastric hemorrhages or erosions as a sign of disturbed microcirculation in fatal hypothermia.

Introduction

The normal human core body temperature is approximately 37 °C, maintained by a balance between heat load and loss; heat is produced in the oxidative metabolic process and acquired from the environment, and is lost by conduction, radiation, and evaporation involving sweating and insensible heat loss (mainly, moisture loss from the skin and lungs). The thermoregulatory center, located in the preoptic anterior hypothalamus, is affected in systemic hyperthermia and hypothermia. These systemic thermal disorders usually occur in unusual environments accidentally; however, fatalities may occur with abuse or neglect, which is of forensic concern, whereas those of deprived people, and at work and during sports are of social concern. The victims mostly include children and elderly people, who are susceptible to extreme temperatures. These fatalities may also involve predisposing health conditions and individual susceptibility, including inadequate nutrition, alcohol or drug abuse, trauma, and mental or physical disability. Adverse or toxic effects of drugs and other chemicals can also induce systemic thermal disorders.

Hyperthermia

Social and Forensic Issues

Systemic hyperthermia occurs in a hot environment (exogenous hyperthermia) or by a rise in body temperature due to excess heat generation (endogenous hyperthermia). A typical condition that causes exogenous hyperthermia is extreme exertion in an inadequate environment involving high temperature and humidity (exertional hyperthermia); however, the contribution of predisposing health conditions and individual susceptibility should be considered as usually only some people are affected under the same conditions; these include pre-existing disease (e.g., cardiac and cerebral disorders, and dermatitis), obesity, physical weakness, inadequate nutrition, alcoholism, and use of diuretic, neurotropic, and anticholinergic drugs, as well as heavy clothing.

Apart from incidental hyperthermia due to intolerably hot ambient temperature during summer heatwaves, exogenous fatal hyperthermia can occur under various situations involved in abuse or neglect, and social issues related to healthcare, work, and sports or recreation. Child abuse and neglect are major issues of forensic interest, for example, confined in a small compartment, or left in a room or automobile unattended in summer. In winter, however, inadequate use of heating can cause infantile casualties. Elderly fatalities during

prolonged heatwaves occur frequently with a lower socioeconomic status or social deprivation; however, fatalities of healthy young adults (e.g., athletes, laborers, and military recruits) are not rare; deliberate or even torturous exposure to extreme conditions is a forensic issue.

Malignant hyperthermia induced by anesthetics, associated with a genetic predisposition, is regarded as a form of endogenous heat generation. A similar disorder is involved in the toxicity of drugs and other chemicals, especially illicit drugs, and the adverse effect of a spectrum of therapeutic drugs. These raise clinical and medicolegal issues.

Pathophysiology and Clinical Manifestations

Heatstroke and related syndromes

The human body is more susceptible to an elevated body temperature than to a decrease; both exogenous and endogenous hyperthermia is life threatening. Hyperthermia involves water and salt depletion due to perspiration, presenting with various clinical manifestations, which may be classified into four classic forms: (a) Heatstroke: a fatally severe condition involving thermoregulatory disorder, characterized by hot and dry skin, and cerebral dysfunction involving confusion, as well as tachycardia and hyperventilation, accompanied by hyperpyrexia (often over 40 °C), resulting in vascular collapse, coma, rhabdomyolysis, and multiple organ dysfunction syndrome (MODS) ultimately. (b) Sunstroke: a form of heatstroke caused by excessive exposure to the sun's rays, presenting with hypotension, tachycardia, and cold sweat due to vascular collapse, often without hyperpyrexia. (c) Heat exhaustion: a form having a continuum with heatstroke, mainly resulting from hypotonic dehydration due to excessive sweating (hyperhidrotic heat exhaustion), marked by prostration, weakness, fainting, and vascular collapse, usually with nearly normal body temperature; otherwise, a thermal disorder accompanied by failure of sweating (ahidrotic heat exhaustion), possibly due to dysfunction of the sweat mechanism. (d) Heat cramp: usually nonfatal, painful muscle spasms with headache, thirst, and hypotension but without hyperpyrexia, induced by exertion in a hot environment, typically related to salt deficiency, partly including possible exertional rhabdomyolysis, and sometimes associated with hyperventilation, alcohol abuse, or ill health.

The human body can be fairly well adapted to a hot environment (acclimatization); however, an extreme environment in combination with predisposing factors and individual susceptibility ultimately impairs thermoregulation, and the body temperature rises precipitously in association with a failure to sweat. High humidity interferes with the dissipation

of heat from the skin. Obesity is a risk factor due to increased load on the heart, increased metabolic heat, reduced heat loss because of the large volume-to-area ratio, and extra insulation by fat. A rise in the body temperature results in generalized vasodilatation, reducing circulatory blood volume. Lowered peripheral resistance enhances venous return and increases cardiac output, leading to elevated venous pressure that induces high-output cardiac failure and circulatory collapse, and can ultimately extinguish sweating. A rise of body temperature increases the metabolic rate (around 10%/1 °C), subsequently increasing tissue oxygen consumption; however, alkalosis and increased blood flow impair oxygen supply to the tissues from blood, resulting in decreased arterial and increased venous oxygen saturation. Thus the main pathophysiology of heatstroke consists of hyperpyrexia involving impaired thermoregulation, accompanied by dehydration due to extreme sweating, and profound systemic hypoxia. An individual who survives the acute phase develops further complications of pneumonia secondary to pulmonary edema, renal tubular necrosis, adrenal hemorrhage, hepatic necrosis, myocardial necrosis, rhabdomyolysis, systemic inflammatory response syndrome (SIRS), disseminated intravascular coagulation (DIC), and MODS ultimately.

Children and elderly people are apparently more susceptible. A child's small body with a large area-to-volume ratio is easily affected by ambient temperature, and physical immaturity is predisposed to thermoregulatory disturbance because of lower sweating capacity and a high metabolic rate, which is aggravated by excessive self-exertion involving crying and struggling. The elderly can develop heatstroke without substantial exertion due to physical, mental, and social predispositions, including diminished physical compensatory capacity, debilitation, physical and mental disability, and inadequate nutrition, as well as a low socioeconomic situation and social deprivation. Sedentary (nonexertional) hyperthermia of the elderly during heatwaves usually occurs around the end of the first week as a result of gradual deterioration of the heat-adaptive function.

Drug-related hyperthermia

Malignant hyperthermia is a rare life-threatening condition, caused by specific drugs used for anesthesia, including a halogenated volatile anesthetic and succinylcholine (neuromuscular blocking agent). The patient has an autosomal dominant genetic defect causing disruption of intracellular calcium homeostasis involved in excitation-contraction coupling in skeletal muscles. Exposure to a trigger drug causes and sustains an unusually high myoplasm calcium level and persistent skeletal muscle contraction, resulting in a marked increase in oxidative metabolism, leading to a serious condition with a rapid rise in body temperature, including tachycardia, skeletal muscle rigidity, arterial hypoxemia, metabolic and respiratory acidosis, electrolyte disturbance involving hyperkalemia, profound hyperthermia, circulatory collapse, and death if not treated promptly. In addition, some illicit drugs (e.g., amphetamines) can cause severe hyperthermia, accompanied by rhabdomyolysis (drug-induced hyperthermia). A spectrum of other drugs, mainly including narcotics, psychotropics, and analgesics, can induce rhabdomyolysis with hyperthermia, which is called 'malignant syndrome.' 'Serotonin syndrome'

is a similar drug adverse effect of selective serotonin reuptake inhibitor (SSRI, antidepressant).

Autopsy Findings

Macropathology

External findings:

There is no specific pathology of fatal hyperthermia; however, it is important to note findings related to predisposition (e.g., general condition, skin disease, and drug abuse) and physical abuse or neglect as well as those needed to differentiate other insults. Intradermal multiple petechial hemorrhages in the chest and extremities can be a sign of prolonged death involving DIC and MODS. An extraordinarily high rectal temperature in the early postmortem period, with reference to rigor and lividity, may suggest death involving hyperpyrexia, although other fibril diseases and traumas should be excluded.

Internal findings:

The aim of pathology in the context of a diagnosis of fatal heatstroke is first to exclude other insults, and second to detect findings compatible with heatstroke, although they are not specific. These include punctate hemorrhages in the intrathoracic (pleural, pericardial, and epicardial) serosa, cerebral periventricular petechiae, and pulmonary and/or cerebral edema in short survival case, and cloudy swelling of the skeletal muscle and other viscera with edema, and overall serosal and mucosal multiple hemorrhages, suggesting DIC and MODS in prolonged deaths. Dark red or brown urine suggests myoglobinuria. Postmortem CT morphology of the lungs presents findings similar to congestive heart failure.

Histopathology and immunohistochemistry

Histology demonstrates the findings of MODS compatible with fatal heatstroke, including pulmonary edema with/without secondary pneumonia, renal tubular necrosis, adrenal hemorrhage, hepatic centrilobular necrosis, acute pancreatitis, myocardial necrosis, rhabdomyolysis, cerebral edema with diffuse neuronal injury involving Purkinje cell necrosis, DIC, and SIRS. Myofiber hypercontraction necrosis and plaque-like signs of decomposition are characteristic of drug-induced malignant hyperthermia.

Possible immunohistochemical markers include heat shock proteins, ubiquitin, catecholamines, and chromogranin A to detect a systemic response to thermal stress, and myoglobin to detect rhabdomyolysis. Low dopamine and chromogranin A positivity in the hypothalamus, and high noradrenaline and dopamine positivity in the adrenal medulla are possible indicators of a prolonged systemic response to prolonged hyperthermia. Patchy myoglobin loss in skeletal muscles with deposition in the kidneys indicates rhabdomyolysis.

Toxicology

Toxicological screening is important to evaluate the contribution of alcohol and drugs to predispose accidental hyperthermia, and to detect drugs and other chemicals that can induce systemic hyperthermia and rhabdomyolysis: malignant hyperthermia, malignant syndrome, and serotonin syndrome.

Biochemistry

Clinical findings: Biochemical findings are crucial for a clinical diagnosis of heat stroke. Serum electrolyte changes vary by case, but hyperkalemia is a sign of poor prognosis. Hepatic damage is evident, for example, as indicated by elevated serum aspartate aminotransferase (AST; SGOT) and lactate dehydrogenase (LDH) levels. Elevated serum creatine phosphokinase (CPK) level, myoglobinemia, myoglobinuria, and hypocalcemia indicate rhabdomyolysis. Hyperventilation causes alkalosis, but acidosis can result from lactic acidosis and/or renal failure involved in MODS. Elevated blood urea nitrogen and creatinine indicate combined influences of dehydration, skeletal muscle damage, and renal failure. Other findings indicative of SIRS, DIC, and MODS are signs of poor prognosis. Elevated serum procalcitonin and growth hormone levels were reported in heatstroke survivors.

Postmortem findings: Biochemistry is also important in postmortem investigations; findings that indicate dehydration, electrolyte disturbance, systemic skeletal muscle damage, SIRS, and MODS involving renal, hepatic, cardiac, and pulmonary damage can be detected. In early death without MODS, elevated creatinine levels in blood and body fluids indicate skeletal muscle damage; however, infantile and elderly subjects only present with signs of dehydration, as indicated by an elevated urea nitrogen level and electrolyte disturbance. Catecholamines, serotonin, and chromogranin A in blood and body fluids are possible indicators of stress responses to prolonged thermal stress.

Molecular Pathology

Hyperthermia along with an increased metabolic rate leads to protein denaturation in viscera, involving damage to membrane integrity, the cytoskeleton and nucleus, and ultimate cellular death. These processes involve systemic activation of biomarkers related to self-protection, inflammation, and repair, which include cytokines, chemokines, anti-apoptotic factors, and cell components.

Key Points of Diagnosis

Clinical diagnosis of heatstroke and related syndromes is usually not difficult, considering hyperpyrexia and laboratory findings, and excluding other causes of hyperpyrexia, but early diagnosis and management is needed to improve prognosis; however, postmortem diagnosis is obstructed by a lack of specific findings. The diagnosis should be established by collecting pathological findings compatible with heatstroke, related to the predisposition, drug abuse, and physical abuse or neglect, and for differentiating other insults, in combination with toxicology and biochemistry. Circumstantial evidence may also be considered when available.

Hypothermia

Social and Medicolegal Issues

Systemic hypothermia occurs due to cold exposure, or is induced by drugs, or artificial cooling for therapeutic purposes.

Hypothermia in a cold environment is usually accidental, predominantly due to a cold climate (environmental hypothermia), but is often associated with alcohol or drug abuse, or illness, including debilitation, inadequate nutrition, and metabolic or endocrinological disorders. The contribution of individual susceptibility should also be considered. Cold exposure may induce a cardio- or cerebrovascular accident.

Most victims of environmental hypothermia are children and elderly people, involving abuse or neglect, or healthcare problems. In particular, abuse and neglect are major issues for children, and elderly fatalities in the cold season are frequent with a lower socioeconomic status or social deprivation; however, fatalities in healthy young adults (e.g., athletes, laborers, and military recruits) can occur in inadequate or accidental conditions, even during recreation (e.g., hiking and skiing), often accompanied by exhaustion, raising social and legal issues. Another situation is immersion hypothermia in cold water, for example, in shipwrecks and/or falling into ice-cold water. Fatalities in therapeutic hypothermia involve medicolegal issues.

Pathophysiology and Clinical Manifestations

The human body can be poorly adapted to a cold environment, and systemic hypothermia occurs due to uncontrollable lowering of the core body temperature (usually below 35 °C); this involves enhanced loss and reduced production of body heat under the influence of various factors: (a) environmental factors, including low temperature (not necessary below 0 °C), wind/air movement, contact heat loss from the body, and wet clothes/body; (b) physical factors, including poor body fat mass, children and elderly people, and alcohol intake; (c) reduced heat production, for example, due to inadequate nutrition, debilitation, and metabolic or endocrinological disorders (e.g., hypothyroidism and hypopituitarism); (d) impaired thermoregulation, for example, due to exhaustion, alcohol or drug intoxication, aging, and cerebrovascular disease or head injury. In addition, various factors interfere with escape: (a) disturbed consciousness, for example, due to cerebrovascular disease, head injury, alcohol or drug intoxication, metabolic coma, and mental disorder; (b) physical or mental disability, for example, due to exhaustion, disease, and trauma; (c) low socioeconomic status; (d) disaster, and physical abuse or neglect.

In a cold environment, the human body conserves heat by vasoconstriction in the skin and muscles, and compensates for heat by shivering and an increased cellular metabolic rate, initially accompanied by elevated blood pressure (so-called 'excitation phase'). The subcutaneous fat layer serves as an insulator. Thus the body temperature is maintained (compensation phase). Cold diuresis, induced by depressed renal reabsorption and relatively increased central blood flow, decreases body fluid, causing hemoconcentration, which is aggravated by leakage of plasma into the extracellular space (cold edema). The body temperature falls below 35 °C in extreme cold, causing mental and physical disorders with maximum respiratory stimulation but without hypotension (decompensation phase; mild hypothermia).

Compensatory heat production can function to about 32 °C, below which body temperature rapidly decreases,

shivering ceases, and metabolic processes and the cardio-pulmonary status deteriorate (paralysis phase; moderate hypothermia). Thus respiration becomes less frequent and shallower, and the pulse rate decreases with hypotension. Below about 28–30 °C, cerebral dysfunction is apparent, presenting with analgesia, consciousness disturbance, hallucinations, often involving ‘paradoxical undressing’ or ‘hide and die,’ and diminished reflexes; the thermoregulatory center loses its function, and narcosis appears, finally resulting in loss of reflex (collapse phase; severe hypothermia). Cardiac function is also depressed, showing bradycardia, arrhythmia, prolonged PQ, widened QRS, and flattened/inverted T-waves on an electrocardiogram. Atrial fibrillation often appears at 30 °C, below which vital signs diminish progressively with significant hypotension and possible development of pulmonary edema. Ventricular fibrillation occurs finally at 22–28 °C. Electrolyte disturbance and metabolic acidosis also affect cardiorespiratory function. Below about 20 °C, vital signs are hardly detectable with a flat electroencephalogram and bradycardia progressing to asystole (profound hypothermia). The lowest body temperature in accidental hypothermia survival was reported as approximately 14 °C.

Victims often have localized skin lesions: Chilblains are mild lesions usually in the peripheries, including the hands, feet, ears, and nose, and also on the elbows and knees, presenting with erythema, bluish or pale areas on the skin with edema, occasionally accompanied by blisters or ulcers. These lesions are a consequence of persistent or intermittent cold exposure (not necessary below 0 °C), usually in combination with high moisture, caused by impaired microcirculation, involving peripheral vasoconstriction, blood sludge due to cold agglutinins, endothelial damage, and edema, partially depending on individual predisposition. Frostbite is a more severe form, involving local skin tissue destruction, usually on the hands, feet, ears, and nose, directly caused by freezing cold, as a consequence of stagnant blood flow and edema due to paralytic vasodilatation in combination with inflammation and necrosis. The severity of this lesion is classified into four degrees: (1) erythema, (2) superficial vesiculation, (3) hemorrhagic blisters involving microvasculature, and (4) damage to deeper tissues; these depend on the temperature and duration of cold exposure and individual factors.

Survival time in dry cold can vary widely, depending on multiple factors other than temperature (e.g., wind velocity, humidity, and flooring material) but usually not shorter than hours. Immersion in cold water causes more rapid loss of heat. Previous reports described that survival time in immersion hypothermia was about 2 h in water for shipwreck victims, half an hour in water at 0 °C, and was possibly nonfatal in water at >20 °C; however, immersion in ice-cold water may result in fatal neurogenic shock.

Alcohol intake is a well-known risk factor because of vascular dilatation in the skin predisposed to heat loss, suppressed shivering due to skeletal muscle relaxation, and interference with physical and mental activity. Ethanol also antagonizes ketonemia induced by hypothermia, and impairs metabolic heat generation using ketones; however, opposite observations involving alcoholic survivors who recovered from profound hypothermia have been reported. These are attributed to the protective effect of alcohol against cardiac fibrillation or

on the brain by increased blood perfusion and reduced oxygen consumption.

Infants are much more susceptible to hypothermia than adults because of their small body with a larger surface area to body mass ratio and a thin subcutaneous fat layer, which enhances heat loss per body mass. Poor muscle volume allows less compensatory increase of heat production, which contributes to chemical thermogenesis by shivering. Newborn infants for a few weeks after birth need special care to avoid hypothermia because of immature thermoregulatory function; mortality is quite high when neglected. Susceptibility of the elderly is apparent when deteriorated physical and mental abilities as well as frequent complications of debilitating diseases are considered; these conditions are readily aggravated by inadequate nutrition, low socioeconomic status, social deprivation or neglect.

The status of ‘suspended animation’ is a special medicolegal issue in systemic hypothermia. Advanced hypothermia involves an extremely lowered metabolism; an individual can survive with very low oxygen in the body under a condition in which vital signs cannot be detected clinically, ready for recovery without significant mental or physical deficit by adequate medical management. Such examples often include children, despite their susceptibility to hypothermia. The combined effect of narcotic intoxication or a state of sub-nutrition, which decreases the metabolic status, may also be considered.

Autopsy Findings

Macropathology

External findings: Classic signs of prolonged cold exposure should be noted, although these are not always present or are not specific. These include cherry-red postmortem lividity, which reflects increased blood oxyhemoglobin, and erythema (chilblains and frostbite) as local signs of cold exposure (Figure 1). It is also important to note pathologies related to the predisposition (e.g., general condition, head trauma, and drug abuse) and physical abuse or neglect as well as those for excluding other insults. An extraordinarily low rectal temperature in the early postmortem period, with reference to rigor and lividity, and ‘paradoxical undressing’ may suggest death involving hypothermia.

Internal findings: The pathology of viscera is not uniform, largely depending on the death process and survival time, which are related to the severity of cold exposure (environmental factors) and the tolerance of victims; however, classic signs of fatal hypothermia are frequently detected: cherry-red lungs with mild edema, suggesting cold air inhalation, a striking difference between bilateral heart blood colors (bright red in the left and dark red in the right) depending on their blood oxyhemoglobin saturation (Figure 2), clotting of cadaveric blood after preservation (retained coagulability), multiple dark-brownish punctate gastric hemorrhages or erosions (Wischnevsky spots) as a sign of disturbed microcirculation (Figure 3), and relatively intact other viscera with mild edema; however, complications of pneumonia and predisposing diseases are not rare. Hemorrhages in large muscles (especially the iliopsoas) have been reported. Postmortem CT demonstrates diffuse alveolar inflation (hyperaeration) of the lungs

Figure 1 Erythema at the knee joint (a) and the histology (b), showing hyperemia and edema (HE, 40 $\times$).

Figure 2 Marbling of bilateral heart blood in the pericardial sac after removing the heart.

with mild edema, hematoma in the iliopsoas, and urine retention in the bladder.

Histopathology and immunohistochemistry

The histology of chilblains involves dermal edema and congestion, occasionally accompanied by inflammatory cell infiltrates, different from subcutaneous hemorrhages. Internal viscera often do not show evident morphological signs of cellular damage; however, precise histology detects vacuolization of cardiomyocytes, hepatocytes, and adrenal, pancreatic, and renal tubular cells. Vacuoles in the anterior pituitary gland cells are indicative of prolonged hypothermic death, often detected in adrenocorticotrophic hormone (ACTH) cells, followed by gonadotrophs, but infrequently in thyroid-stimulating hormone (TSH) cells. Erythrocyte sludge may be seen in small blood vessels, accompanied by microinfarcts of the viscera.

The histology of Wischnowsky spots is focal pigmentation with hemoglobin immunopositivity in the gastric epithelia, often without erosions. With regard to stress responses to cold, previous immunohistochemical studies demonstrated increased expressions of heat shock protein (HSP)-70 and ubiquitin in the kidney, liver, lungs, and pancreas. Renal

ubiquitin immunopositivity is increased. Chromogranin A immunopositivity is low in the hypothalamus neurons, suggesting a prolonged stress response to cold.

Toxicology

Toxicological screening is important to evaluate the contribution of alcohol and drugs to the predisposition to accidental hypothermia, and to discriminate intoxication.

Biochemistry

Clinical findings: Systemic hypothermia involves dehydration, accompanied by increased concentrations of various blood constituents (e.g., erythrocytes, serum proteins, and urea nitrogen). Serum glucose is elevated due to glycolysis in the initial phase. In advanced hypothermia, however, hypoglycemia and elevated serum amylase are common. Increased ketone bodies suggest enhanced fat metabolism.

Postmortem findings: Typical findings include respective high and low oxygen saturations of left and right heart blood, azotemia (increased urea nitrogen) without significant elevation of creatinine and C-reactive protein (CRP), and ketosis (acetonemia); however, ketosis may not be evident in cases involving alcohol intake, but serum CRP may be elevated due to complications of pneumonia. Signs of myocardial and brain damage are usually mild, and even blood catecholamine levels are lower than in other fatalities; however, urinary catecholamine levels are increased. Chromogranin A is low in the blood but high in the cerebrospinal fluid, suggesting prolonged cold stress. Pericardial brain natriuretic peptide (BNP) is often increased, suggesting heart failure before death. In most cases, elevation of the serum amylase level is milder than in other fatalities, mostly including salivary fractions.

Molecular Pathology

Hypothermia may trigger systemic macrophage tumor necrosis factor (TNF)- α production and further neural preconditioning stimuli dependent on TNF- α . Postmortem investigation of humans demonstrated damage to the interstitial matrix and

Figure 3 Whischnevsky spots (a) and the histology (b), showing focal necrosis and pigmentation (HE, 40×).

mild activation of cytokines in the lung, and intact pulmonary surfactants.

Key Points of Diagnosis

Clinical diagnosis of hypothermia is usually not difficult when an extremely low body temperature and laboratory findings are considered, excluding other causes of hypothermia, especially narcotic drug intoxication, and metabolic disorders or endocrinopathies; however, the status of 'suspended animation' should be carefully considered in determining death.

In contrast, poor specific pathology may obstruct a post-mortem diagnosis of hypothermia as the cause of death. The diagnosis should be established by collecting pathological findings characteristic of hypothermia, those related to the predisposition, drug abuse, and physical abuse or neglect, as well as for differentiating other insults, in combination with toxicology and biochemistry. A cold-induced cardiac or cerebrovascular accident should be excluded. Circumstantial evidence may also be considered when available.

Glossary

Amperage Amperage, also called current, is the amount of electric charge passing a point in an electric circuit. The SI unit of electric current is the ampere (A) named after the French physicist André-Marie Ampère.

Electrical resistance The electrical resistance of an object (e.g., human tissue) is defined as the ratio of voltage across it to current through it. This proportionality is called Ohm's law.

Joule heating Passage of an electric current through conductive material (e.g., human tissue) releases heat which is proportional to the square of the current multiplied by the electrical resistance of the conductor. The conversion from electrical to thermal energy results in a local rise of

temperature possibly causing burns, for instance, electric marks on the skin.

Ventricular fibrillation Ventricular fibrillation (VF) is a life-threatening cardiac arrhythmia in which there is uncoordinated contraction of the heart ventricles so that they fail to pump blood into the arteries. The underlying condition is characterized by disorganized electrical activity. If VF continues, it mostly will be followed by cardiac arrest and brain damage due to cerebral hypoxia. Defibrillation (electric discharge of direct current from a defibrillator) may reverse VF.

Voltage Voltage (electrical tension) means the difference in electric potential energy between two points; it is measured in volts (V).

Introduction

In spite of the increasing use of electrical energy, statistics show that the number of accidents caused by electricity is declining. This tendency is apparent for fatal and nonfatal accidents and can be observed both in industrial and domestic surroundings. As electrocution is relatively rare, at least in developed countries, deaths due to the passage of electric current are not always recognized in the external postmortem examination. If the situation at the scene and the findings on the body do not provide unambiguous evidence suggesting electrocution, this cause of death may remain undetected.

In the low-voltage range (<1000 V), electrical accidents occur mostly when touching a live electroconductive object or surface. If the electrical current does not cause any biological damage, this is called an inconsequential flow of electricity through the body. Accidents caused by electricity play a special role within the field of traumatology because of their high lethality.

Low-Voltage Effects

Electricity can harm the human organism in two ways:

- By triggering *excitation processes* in muscles and nerves ('physiological effects') and
- By transformation to *heat energy* resulting in thermal tissue damage (Joule burn).

Low voltage is mainly dangerous because of its effect on the myocardium: When electric current passes through a body, it may cause fatal *ventricular fibrillation*. The risk of fatal cardiac arrhythmias depends on numerous external and internal factors including:

- The type of current (AC = alternating current, DC = direct current): AC is more likely to generate cardiac arrhythmias

and to prevent a person from releasing an electrical source due to tetanic spasm of the muscles. In AC, the number of cycles per second (Hertz) usually is 50 (household current in Europe) or 60 (in the US).

- The time of the electric shock in relation to the vulnerable period of the heartbeat, which corresponds to the relative refractory period and the ascending leg of the T-wave in the ECG.
- Duration of current exposure (contact times of <100 ms are usually not dangerous; if the current continues to flow through the body for an extended time, the amperage threshold triggering ventricular fibrillation may decrease to about 50 milliamperes [mA]).
- Route of the current through the body (if the electric current passes from hand to hand, a smaller part flows through the heart than if it flows from hand to foot).
- Age: With increasing age, the lethality of electrical accidents rises probably because of the higher prevalence of pre-existing heart conditions.
- Amperage A as a function of the given voltage V (usually ranging from 110 to 400 V in households and industrial plants) and resistance R (total of body and contact resistance). The amount of current flow is directly related to the voltage and inversely related to the resistance according to Ohm's law ($A = V/R$).

The effects of current on the human body mainly depend on the amperage, the exposure time, and (in the case of alternating current) also on the frequency. A current of approximately 15 mA ranging clearly below the fibrillation threshold may cause persistent contraction of the affected muscles preventing release of the electric line ('hold-on effect').

The probability of *thermal tissue damage* rises with increasing current density. As a consequence, a local skin burn is more likely when the contact area is small. Further parameters are the specific resistance of the tissue passed and the duration

of the contact. In the low-voltage range, the thermal effects of electricity are mostly confined to the skin. In the case of electrocution, the initially high resistance of the skin rapidly decreases due to the structural damage of the epidermis. If the victim does not succeed in breaking away from the conductor, the skin will become cratered and charred thus largely losing its protective function.

Electric current has been called an 'anonymous threat': Humans do not realize electromagnetic fields surrounding charged conductors. The well-known fact that very short contacts with an electric source can be survived without damage induces people to underestimate the risk of fatal ventricular fibrillation, especially in electrocution from alternating current. If the frequency is very high, the current will primarily cause thermal damage at the interface with the electrode (e.g., in surgical high-frequency cauterization).

In most electrical accidents, the victim's body acts as a link between a live conductor and the point of grounding. The current flowing through the body is limited by the total resistance composed of the insulation from ground on the one hand and the body resistance on the other hand. If the current passes to earth, the contact resistance depends on the clothing (especially the soles of the shoes) and the insulating effect of the surface underneath. Body resistance is mainly determined by the skin, namely its properties at the contact sites; internal resistance is comparatively low.

With increasing thickness of the horny layer skin resistance rises. When the skin is damp (e.g., from sweating, soap suds, or bathwater), skin resistance drops sharply. Sweating is particularly strong under physical stress and at high ambient temperatures; in the presence of high humidity (damp rooms), sweat cannot evaporate, which makes contact with a charged electrical source more dangerous.

Electric burns are due to the local effect of Joule heating. Thermal skin damage is intensified by high amperage, a small area of contact, and long exposure to the current. However, even fatal electrocution does not necessarily leave any electric marks if the contact area is large and skin resistance is small (e.g., in a water-filled bathtub). It is estimated that in about 30% of all low-voltage fatalities no electric marks are

discernible on the body surface, whereas surviving victims may show distinct electric marks in the form of second- and third-degree burns.

In the residential voltage range, faulty insulation of electrical devices, power points, connectors, adapters, and extension cords is a particularly frequent cause of accidents. Very often these occur in damp rooms (e.g., bathrooms) where even an intact appliance (with charged parts protected against touch) may become the origin of currents, for instance if a hair dryer drops into a grounded bathtub (accidentally, in suicides, or homicides). A ground-fault circuit interrupter generally prevents fatal electrocution by disconnecting the circuit in a split second.

Apart from the already mentioned method of committing suicide in a bathtub filled with water, *suicides* using electricity are rare in spite of the general availability of power sources. In the remaining cases, conductors such as bare wires are attached to various parts of the body (wrists, ankle joints, fingers, toes, trunk, neck, or head), sometimes in combination with timers to start the current flow (Figure 1). Suicidal electrocution is predominantly committed by persons who are familiar with electrotechnical matters ('occupation-related suicide').

In cases in which the electrodes are fixed in the genital and/or anal region and/or to the nipples, the possibility of an accident in the context of *autoerotic practices* must also be taken into account. In such deaths from 'electrophilia,' usually pornographic material is found at the scene.

To recognize lethal low-voltage accidents, a careful external *postmortem examination* is essential. If a body is found under circumstances suggesting a premortal effect of electric power, an autopsy is indispensable. Apart from any electric burns, the *premortem symptoms* and the conditions under which death occurred may also point to electrocution: tetanic muscle contractions, grasping an electrical wire, sudden screaming with subsequent loss of consciousness and absence of pulse, sudden fall while near a charged source.

By identifying electrocution as the real cause of death, the investigator helps to protect other persons being exposed to the same source of danger. The evaluation of deaths in a bathtub is particularly difficult and challenging. In the absence of any electric marks, the diagnosis of electrocution can sometimes

Figure 1 Suicide by electrocution: Circular electric burns from contact with naked wires originally wound around the left middle finger (a) and the right second toe (b).

be made only *per exclusionem* and on the basis of the electro-technical findings. Under criminalistic aspects, it has to be clarified whether the electrocution in the bathtub is to be interpreted as an accident, suicide, or homicide.

Electric Burn

The most important sign of electrocution is the electric mark. Its appearance resembles a local second- to fourth-degree burn which is caused by Joule heating. The *morphology* of an electric mark depends on numerous modifying influences: shape and surface structure of the conductor, amperage and current density, duration of contact, and skin resistance (dependent on the thickness of the horny layer and dampness). Under special circumstances, the size and shape of the conductor may be reflected by a congruent ('patterned') electric burn (Figures 2 and 3). Such marks are localized at the contact sites of the charged conductor and/or at the point of grounding. Most often, the hands are affected (Figure 4).

On the friction skin with its thick horny layer [digits, palms, and soles; Figure 5(a) and 5(b)], electric marks are macroscopically discernible as blister-like skin lesions with elevated grayish margins, whereas the center often shows yellowish-brown discoloration or charring with tiny perforation holes and fused nodules of keratin; surviving victims may develop

fluid-filled burn blisters within a short time. In body regions covered with thin-layered skin, the electrothermal lesions are rather uncharacteristic and all that may be seen are parched brown areas (Figure 5(c)).

On *histological examination* (Figure 6), the electric marks typically reveal stretching of the basal epidermal cells and their nuclei producing a palisade-type appearance in combination with 'honeycombing' (vacuoles/micro-blisters formed by vaporized tissue fluid and located especially in the corneal layer). Differentiation from burns not caused by electricity can be difficult; one characteristic feature of electric burns is their inhomogeneity (dependent on the structurally different resistance behavior: for example, good conductivity along the sweat ducts). Metal traces from the conductor deposited at the site of contact ('metallization') can be proved by histochemical reactions or atomic absorption spectrometry (AAS). In principle, electric burns can also be of postmortem origin and are therefore no reliable proof that the electric shock occurred before death, unless the survival time was long enough for an inflammatory response of the affected tissue or for the development of fluid-filled burn blisters.

The *internal findings* seen in electrical fatalities are usually unspecific. Because of the diagnostic problems outlined above, careful examination of the death scene with regard to potential power sources is essential in every case in which electrocution is suspected.

Figure 2 Medial side of the right foot, which touched a bare wire (230 V) while unclothed. Linear electric burn above the arch with wrinkled detachment of the epidermis.

Figure 3 Left foot with linear electric burn on the friction skin of the heel. Grayish white electric burn with slightly raised margins. The box in the left lower corner shows the histological view with a large gas bubble in the stratum corneum and elongation of the basal epidermal cells.

Figure 4 Accidental electrocution with multiple skin burns on both hands, to some extent in combination with metallization. The detached epidermis partly peeled off as it stuck to the surface of the conductor.

Figure 5 Close-up views of low-voltage burns on friction skin (a, b) and nonfriction skin (c).

High-Voltage Effects

In contrast to low voltage, the effects of high-voltage electricity may also cause delayed deaths, although 4/5 of the victims still die at the site of the accident, mostly from cardiac arrhythmia (ventricular fibrillation). The survival time of the remaining fifth varies depending on the degree and extension of the burns suffered.

Some textbook authors state that deaths caused by high voltage are always easy to recognize. However, as electric marks are very variable in shape and appearance, even high-voltage electrocutions may remain undetected (Figure 7). In cases of a firm and only short contact, the electric marks may

resemble low-voltage lesions. Nevertheless, most high-voltage effects on skin differ from the 'standard' appearance of electric marks as they are known from exposure to domestic voltage (blisters showing pale raised margins). Local thermal damage includes crater-like lesions, deep charring, and severed tissues.

In about half of all high-voltage accidents with a fatal outcome, extensive burns are seen. These are mostly due to *arcing* from the conductor to the body of the victim. If a person comes near a high-voltage electric conductor, an electric arc forms between the conductor and the body. The temperature in the center of such an electric arc may reach several thousand degrees Celsius. The arc marks on skin and clothing are characterized by a multitude of scattered individual or confluent

Figure 6 Histological sections of an electric burn showing micro-blisters within the detached horny layer (a) and 'streaming of the nuclei' in the basal layers (b).

Figure 7 Burn hole in a sock (a) corresponding to a small electric mark on the great toe (b) from arcing to ground.

burns producing a 'crocodile skin' effect. On shoes, the leather uppers and sometimes even the soles show punctured perforation holes with scorched margins. Flash burns from arcing or flame burns from ignited clothing may cause extensive heat damage involving nearly the whole body surface. Apart from mostly third-degree skin burns, singeing of the head, beard, and body hair can be seen; eyebrows and eyelashes may be affected in the same way. Electric arcing sometimes causes grayish-black deposits of material from the conductor ('metallization') on exposed body parts and clothes.

It is self-evident that additional *blunt traumatization* is particularly frequent in high-voltage accidents. Other than with domestic voltage, contact is essentially limited to power lines, overhead cables, transformers, and electric power substations. Consequently, the electric shock often occurs several meters

above the surrounding level and a subsequent fall from a height may cause serious secondary injuries sometimes constituting the real cause of death. As electric marks can be minimal after a short contact with the conductor, fatal occupational accidents should always arouse suspicion of a previous electric shock.

In the face, burns and metallization effects from electric arcing can be spared along the skin folds resembling 'crow's feet.' In the past, crow's feet were interpreted as a vital sign caused by squinting the mimic muscles. Nowadays, an electrically induced contraction of the muscles and thus a potentially supravital origin is assumed. Sometimes, petechial hemorrhages are found in the conjunctivae, the facial skin, and the mucosa of the upper respiratory tract after high- or low-voltage electrocution, occasionally in combination with subepicardial and subpleural

blood extravasations. Some authors have interpreted these findings as signs of 'electrical asphyxia.' As a potential explanation, tetanic contraction of the respiratory muscles with subsequent increase in intrathoracic pressure is discussed.

After *prolonged exposure* to the current, direct and indirect burn sequelae are the dominant effects. The manifestations include extensive charring, a cooked appearance of the muscles, and even bursting of joints. In contact with high-voltage power lines, electrothermal transections of body parts have been observed. If cortical bone is affected, whitish osseous pearls can be present due to local melting and secondary resolidification of bone mineral.

High-voltage fatalities are usually *accidents*, and the victims are mostly men dying while doing occupation-related work near overhead cables (e.g., operating cranes and other high-construction machinery) or in electric power substations. Accidental contact with a high-tension grid transmission cable while using a long metal object (e.g., when harvesting fruits in high trees) is also possible.

Sometimes persons climb parked railway carriages or high-voltage pylons out of carelessness or to prove their courage. Very rarely *suicides* are committed by climbing a high-voltage mast or intentionally approaching power lines (**Figure 8**). Another method is to throw a bag attached to a wire over a power line or an overhead cable (**Figures 9** and **10**).

Lightning Strikes

Lightning is a natural phenomenon of 'atmospheric electricity' based on a sudden environmental discharge of static electricity between a cloud and the ground resulting in a high-voltage direct current of extremely short duration. Correspondingly, the amperage along the path is so high that the thermal radiation causes an explosion-like extension of the air. In damp

materials such as trees, the water evaporates along the lightning path forming high-pressure steam which causes mechanical damage.

If the flash of lightning strikes the ground next to a standing or walking person, a 'stride (step) potential' forms between the feet so that a current flows through the body. Lightning accidents may also be due to a direct strike, a contact voltage (the victim carries a [metal] object struck by lightning), a side splash (after a primary strike to an object the lightning discharges to a victim standing nearby), as well as a wire-mediated strike (e.g., via the telephone line).

The lethality of lightning accidents is estimated at about 30%. Surviving victims often present with thermal lesions and blunt trauma (the latter mostly caused by the blast force) as well as transient neurological sequelae such as paralyses, aphasia, vertigo, and sensibility disturbances, and also cataract or rupture of the tympanic membrane. In fatal cases, the question arises which of the vital functions was the first to fail. On the one hand, death can result from central respiratory paralysis followed by hypoxia-induced secondary circulation failure. On the other hand, electric cardioversion may cause primary cardiac arrest.

The criminalistic significance of lightning injuries is underlined by the numerous possibilities of potential misinterpretation. For example, the absence of conspicuous burns may wrongly suggest death from a natural cause or blunt trauma. Sometimes, the situation at the scene seemingly points to

Figure 8 Suicide by high-voltage electricity. The victim used a long aluminum pole (left foreground) to touch a conductor rope of a high-voltage line. Extensive electric mark with deep tissue transection on the right hypothenar (close-up view).

Figure 9 Suicide by high-voltage electricity: A bare wire was attached to the handles of a bag filled with stones and thrown over the overhead line of the railway. The victim was found lying flat on his back.

Figure 10 Site on the platform where the body was found (upper photograph). The charred deposits correspond with the fourth-degree burns on the back of the body (lower photograph).

homicide (torn clothing and blown off shoes due to water vaporization, concomitant mechanical injuries).

Findings on the *clothing* may include a broad spectrum of mechanical and thermal changes. Holes densely arranged in groups are a typical effect of lightning strikes (comparable with lesions from shotgun pellets). On metallic elements of the victim's clothing (buckles, snap-fasteners, etc.) as well as on watches and pieces of jewelry, small molten beads may be found. Shoes often show tiny holes or circumscribed tears in the sole or the adjacent upper leather. On textiles made from synthetic fibers, uncharacteristic tears can be seen as well as heat changes with local hardening and rolled-in margins with microscopically detectable melting effects (club-shaped fiber ends).

In fatal strikes, the lightning current usually enters in the parietal region singeing the head hair ('fox-red' discoloration, frizzy appearance, and club-like ends of the hairs). Extensive burns on the body surface are sometimes present, but are by no means a constant finding. The lightning current predominantly passes over the surface of the (mostly wet) skin so that only a small proportion of the current flows through the victim's body. This phenomenon is called 'flashover.' The route of electricity is indicated by multiple first- to third-degree burns and singeing of head hair, eyebrows, eyelashes, body, and pubic hair (**Figure 11**).

At the exit sites toward ground, the skin burns may resemble typical electric marks. Metal objects such as a necklace, a watch, or a belt buckle are heated by the lightning current so that they may leave congruent contact burns which are often accompanied by metallization extending also to the intact skin adjacent to the burn.

Figure 11 Singed head hair (a) and pubic hair (b) of a man who was struck by lightning, but survived. Note the tiny burn surrounded by a zone of reddening above the pubic hair (from contact with a metal buckle).

Figure 12 Abdominal wall of a woman who was struck by lightning, but survived. Fern-like reddish pattern on the skin, which is already fading some hours after the lightning strike.

The best-known morphological finding in victims struck by lightning is the so-called Lichtenberg figure, a reddish, fern-like ('arboresque') skin pattern resulting from transient hyperemia (not from intra- or subcutaneous extravasation of blood!), which blanches or disappears after several hours (**Figure 12**). Histologically, Lichtenberg figures consist of small dilated vessels in the corium, sometimes combined with elongation and palisading of the basal epidermal cells.

Neonaticide

NEI Langlois and RW Byard, Forensic Science SA, Adelaide, SA, Australia
C Winskog, University of Adelaide, Adelaide, SA, Australia

© 2013 Elsevier Ltd. All rights reserved.

Introduction

Infanticide is a general term for the murder of a child aged less than 1 year, and filicide is used when the perpetrator is the parent, but neonaticide is used to refer to deliberate killing of a child up to 24 h of age by his or her parent.

Nonhuman primates have been observed to kill their offspring, and the act of neonaticide in human cultures dates back to before historical records were kept. In the past, in some cultures, it was not necessarily a crime; a father's right to murder his children was recognized in Roman law under *patria potestas*, and infanticide was not uncommon in China up to the nineteenth century. Infanticide in Britain in early times was largely a matter for the church but became better recognized as a crime in the Middle Ages.

Incidence

Neonaticide would appear to be uncommon, but it is likely official statistics are an underestimate of the true incidence. A review of cases in France revealed that a variety of factors (including miscoding) resulted in the official published rate (0.39 per 100 000 live births) being lower than the rate disclosed by a retrospective review (2.1 per 100 000) – the higher rate being in accord with an American study. Furthermore, it is probable that a number of cases remain hidden and are not detected.

Males rarely perform the act of neonaticide. Women who commit neonaticide are often young, poorly educated, and unmarried or single. Frequently, they have concealed or denied their pregnancy and have made no plans for caring for their child. However, a married mother who had received some antenatal care was encountered in around 21% of cases in one study. It may not be their first pregnancy, and they may have other children. Thus, it must be recognized that offenders may be of any (reproductive) age, status, educational level, and marital status. Although mental illness may be a feature in some, it is not a common feature and it is more likely in older offenders.

Male and female newborn infants have been regarded as equal victims of neonaticide, although a higher rate of males are suggested in certain communities, which may be a consequence of a higher male than female birth rate. There is no predisposition toward those with congenital abnormalities. The majority of cases are found in the mother's place of residence, such as in the toilet or an associated structure (such as a shed); frequently, the bodies are placed in a rubbish receptacle, but bodies may also be recovered outdoors and from lockers.

Methods

Neonates are small and have no ability to defend themselves. In one case series, strangulation was the most common method of homicide (12 cases), followed by drowning (7 cases) and hypothermia (4 cases). Blunt head trauma was rare (2 cases) as was stabbing (1 case). Other case series agree that strangling, smothering, or suffocation by other means are the most common means of homicide, with less common methods including blunt force and sharp force. Strangulation is easily accomplished by the mother's own hands, whereas drowning may be performed in the toilet. Death may also be effected by inaction, such as abandonment leading to exposure. Some rarer methods include use of opium on the nipples and insertion of a needle into the cranium through the fontanel or via the orbit.

Assessment

When a dead newborn is found and neonaticide is considered, the pathologist has two questions to answer: did the child have an independent existence and if so, what was the cause of death. It is a requirement to prove a child was born live and had an independent existence in order to form the charge of neonaticide (deliberate killing of a newborn in the first day of life). Live birth and separate existence are not clearly defined but can be regarded as maintenance of a circulation and respiration when the child has been completely delivered of its mother, which may be extended to require division of the umbilical cord. If the case can be shown to be that of a stillbirth (death before extraction/expulsion independent of duration of pregnancy) then it will most likely be outside of medicolegal jurisdiction.

A first step toward determining if a newborn may have been born alive requires assessment for signs of maceration, which manifest as redness of the skin with peeling of the epidermis and flaccidity of the body with laxness of the joints (**Figure 1**). Maceration is a sign of death *in utero*, but the changes take several days to develop and the absence of maceration cannot be used to indicate a live birth. A further guide to the likelihood of live birth may be obtained by forming an assessment of gestational age (i.e., if born full term at 40 weeks or premature) as live birth becomes unlikely at under 20 weeks of gestation. Methods to estimate gestational age include assessment of ossification centers, odontological appraisal of development of the teeth buds, and histological examination of tissues with referral to standard texts. A third consideration is for the examination of abnormalities that would be considered likely to result in stillbirth, such as severe malformations (including chromosomal and other genetic syndromes); attention should

Figure 1 Macerated fetus from case of intrauterine death displaying redness of the skin with peeling of the epidermis.

be paid to the placenta, which should be sought for examination.

If it is determined that live birth was possible, the next step is to assess for signs of a separate existence. Tests that have been proposed for proving vitality include the lung flotation test, assessment of stomach content, and examination of the umbilical cord.

The lung flotation test is based on the assumption that an infant who has not breathed will have airless lungs that will sink in water, whereas if breathing has occurred after birth, the lungs will be buoyant in water. However, artificial respiration can aerate the lungs and gaseous accumulation can occur in advanced decomposition, which may invalidate the test. Pneumonia, atelectasis (due to a deficiency of surfactant), and early decomposition can cause the lungs to sink. Histological observation of pulmonary interstitial emphysema has been proposed as a more specific than marker of live birth; however, equivocal changes may occur as an artifact and an absence of pulmonary interstitial emphysema does not exclude live birth.

Examination of stomach contents may provide evidence of an independent existence if milk is found as it indicates the newborn has been able to ingest food, which can be regarded as proof of a period of survival sufficiently long to feed. The presence of air may indicate that gulping had occurred with swallowing of air, but this can be invalidated by resuscitation, which can force air into the stomach. Similarly, the presence of air in the middle ear has been proposed as an indicator of life, but it must be presumed that air could be present due to decomposition or resuscitation.

The infant end of the umbilical cord should show evidence of an inflammatory reaction if there has been a survival of

some hours after birth, which would be good evidence for a period of survival following birth. However, this may be discounted if there is a funisitis of the cord and an absence of inflammation does not exclude live birth.

The pathological findings may not be contributory to the question of whether the child had been born live. The investigator should also consider any witness accounts from the scene, such as any reports of the sounds of a child crying. The determination of an independent existence may be impossible if the remains are decomposed or skeletonized.

If it is possible a live birth had occurred, the pathologist will need to examine the infant to determine the cause of death. In such cases, the assistance of a suitably qualified pediatric pathologist may be sought. The cause of death may be natural but is likely that ancillary tests (including histological and microbiological) that will necessitate expert interpretation will be required. Furthermore, the brain will be markedly softened due to the low level of myelination, such that fixation followed by expert neuropathological assessment should be performed as this would be expected to increase the documentation of pathological lesions. Radiology, including use of CT (computed tomography) and/or MRI (magnetic resonance imaging) may assist in the assessment.

As noted above, the most common means of neonaticide are strangulation and suffocation. Strangulation may be performed by the mother's own hands or by ligature. Suffocation may be achieved by inserting material into the mouth (e.g., a piece of wadding) or by using an object such as a pillow. The pathologist will need to bear the possibilities in mind while performing the external examination and internal dissection. The use of CT may disclose a mass obstructing the airway even when there has been a significant postmortem interval. However, due to the innate weakness of the neonate, there is usually no evidence of defensive action or a struggle and there may be minimal signs; fractures of the hyoid or larynx are unlikely due to the elasticity of the structures. Death caused by smothering from a pillow would be particularly difficult to detect. However, the pathologist should extend the external examination to search for deposited fibers (on the neck or within the oropharynx). The use of histology including modified Poley's acid fuchsin-methyl green has been suggested to visualize microscopic appearance of a neck compression and immunohistochemical staining may reveal changes. The proposed signs of asphyxiation, congestion of the organs, petechial hemorrhages, cyanosis, fluid blood, and dilation of the heart, have been dismissed as an obsolescent quintet. Care must be taken not to misinterpret neck trauma resulting from the mother's efforts to deliver the child or from the cord having been wrapped around the neck during birth. Determination of death by drowning (e.g., by delivery into or by directly pacing into a toilet bowl) may be not distinguishable from stillbirth as both will show a lack of aeration of the lungs with or without fluid in the airway. However, a search should be made in the airways and stomach for aspiration of any material that is also represented in the water of the possible site of drowning.

The newborn may be abandoned resulting in death from exposure by inaction of the mother. It is unclear if signs of hypothermic death develop in the neonate. Blunt head trauma

may be difficult to differentiate from birth trauma and expert neuropathological assessment should be sought; the possibility that a mother has accidentally dropped a newborn would also have to be considered. Other accidental trauma may occur as part of the delivery process. Death due to exsanguination from an umbilical cord that has not been properly clamped or tied should be prevented by natural hemostatic processes, but it has been recorded. The determination of the cause of death may be prevented by postmortem changes of decomposition.

The pathologist may assist with confirming the identity of the mother by taking of samples for DNA comparison with the putative parents. Any items, such as wrappings, with the child should be examined as these may also provide clues to the identity of an unknown mother.

A visit to the scene by a pathologist may provide vital information and should be performed whenever possible. Assessment of the scene may provide valuable information: the use of Lumenol (or other chemiluminescent agent for hemoglobin) may disclose a trail from a site of delivery to the site of the body. In addition, the mother's medical records (including birth and

any psychiatric history) should be obtained from hospitals and medical centers. Questioning of friends and family may provide useful information, particularly, any person who was present around the likely scene of birth. The mother may need medical assistance and should be examined for signs of birth. As soon as possible, she should provide a statement. Wherever possible, the placenta should be retrieved and examined.

Illustrative Case

Some of the findings associated with neonaticide are illustrated by the following case. A newborn child was found partially hidden in the snow behind a fence close to a small sawmill. Blood was spread over a large area (**Figure 2**). The scene examination revealed the presence of a placenta as well as the umbilical cord. The dead child was examined at the scene and signs of blunt force trauma were identified with a palpable skull fracture. Due to the low temperature, the body was well preserved with minimal decomposition. Examination in the mortuary revealed superficial lacerations resembling nail marks from grabbing (**Figures 3 and 4**) and patterned injuries in the shape of a sole of a shoe (**Figure 5**) – it was later established that the mark matched the heel of the shoe the mother wore at the time of the delivery. Autopsy findings included extensive skull fractures with subarachnoid and subdural hemorrhages together with intracerebral and brain stem hemorrhages. It was also established that there was air in the gastrointestinal tract. A national alarm was issued and a vehicle that was suspected to contain the parents was intercepted at the border before it could leave the country. The mother of the child was taken into custody and revealed what had taken place. She claimed that she had been unaware of the pregnancy (it was her second child) and that she had walked off behind the fence to urinate. She gave birth and left the scene shocked and in disbelief of what had occurred. She hid bloody clothing and joined her husband (father of their first child and the newborn) as they began their journey home. When apprehended the father had no knowledge of what had occurred. Death was attributed to blunt head trauma, but hypothermia

Figure 2 The scene of discovery of the body in the snow (see arrows). Blood has been spread by birds preying the placenta and cord.

Figure 3 Abrasion on side of neck (arrow) from fingernail of mother inflicted while grabbing child during birth.

Figure 4 Abrasions caused by mother while grabbing newborn.

Figure 5 Patterned injury from sole of mother's shoe.

in combination with obstructed airways (due to the position of the newborn when found) together with blood loss from the torn umbilical cord was mentioned in the final report as possible contributory factors. Following a trial, the mother was found to have caused the death, but it was also established by the court that she suffered from a psychiatric illness at the time of the act and so she was sentenced to psychiatric care.

Conclusion

The investigation of possible cases of neonaticide may involve many issues. The pathologist should consider utilizing assistance from other disciplines, including pediatric pathologists. In the case example above, it was possible to establish that the child had been born alive and to determine that the mother had caused the death. However, in many cases, it will not be possible to determine with certainty if the child was born alive,

or if live birth is determined the cause of death may remain elusive.

Identification

Introduction

Personal identification is one of the most relevant issues in forensic pathology. In all countries with a structured legal system, cadavers must be formally identified. The reasons behind such obligations are certainly moral and also concern aspects of criminal and civil procedures: in fact, without knowing who the victim of a crime is, it is very difficult to begin investigating and without appropriate identification of the deceased, civil matters such as insurance policies and questions concerning inheritance cannot be concluded. As to what each specific legal system implies as reliable identification, this is another matter. If the body is well preserved, it is frequently sufficient to have family or acquaintances formally, and responsibly, identify the body. But in the case of decomposed cadavers or remains, this cannot or must not be the case, although some judges would like to conclude identification issues (saving on expenses is usually the issue) relying on personal belongings, clothing, or other nonbiological evidence. It is clear that this is incorrect and that biological identification, when possible, should always be sought in order to avoid serious mistakes: Interpol protocols, for one, stress this point.

How to identify a cadaver or human remains is another issue. In this age of DNA, usually, identification is relatively, quickly, and cheaply achieved by genetic testing. Nonetheless, particularly in the case of severely decomposed human remains, many other methods can be as reliable but quicker and cheaper, such as odontology. In many cases, as will be discussed later, particularly in cases of vagrants or when neither antemortem DNA or relatives nor clinical dental or medical data are available, judges and pathologists should be aware that other methods exist.

A final preliminary comment that must be made concerns the degree of confidence and reliability of a specific identification method or rationale. Many different schools exist as to how to classify levels of identification: the two extremes are exclusion and positive (certain) identification. In between, there are a series of nuances that can be summed up as different degrees of compatibility, for example, no elements allowing for exclusion but concordant characters are very general, or several and specific characters with a high identification potential but not sufficient to reach positive identification. The question is how much is enough for positive identification? Unfortunately, there is no real answer. Some methods, such as DNA and fingerprinting, have managed to quantify the degree of correspondence of two biological samples (e.g., the cadaver and the toothbrush of the person whom the cadaver was thought to 'belong to' in life). In other words, a statistical analysis of the frequency of discrete characters (alleles, minutiae) can lead the expert to express the probability of these two samples belonging to the same person as a number (e.g., 98%). Obviously, any method of this sort will be very popular among judges as it has a known error and neatly complies with Daubert and Kumho

rules. Other methods, particularly those based on the comparison of morphology (e.g., odontological and radiological/osteological ones), have more difficulty in quantifying their response. For example, how can an odontologist say what the probability of two different persons sharing the same asset of dental features is? Dental assets change in time and discrete characters are difficult to standardize and study worldwide (although some authors have approached this issue). Or, more simply, what is the probability that two individuals share the same two scars and three tattoos? The answer depends on the types of scars and tattoos, of course, and also on a large deal of subjectivity. Nonetheless, most pathologists will (correctly) continue to identify with morphological and clinical features; one should, however, bear in mind the limits and issues that can be raised with such methods.

The following is a brief survey of identification approaches. The authors wish to stress, however, how the world of identification concerns not only positive identification, that is, matching antemortem with postmortem data (when there already is a possible match), but also cases where there is no clue as to who the body belongs to. This is a frequently underestimated issue, and in these cases, the pathologist must use as many disciplines as necessary to build a biological profile of the cadaver or human remains that should be automatically matched with missing persons databases (when these exist, and hoping the person has been reported missing by someone) and give maximum circulation of the biological profile on newspapers, television, and so on. Thus, the article is divided into two parts: the first dealing with unidentified cadavers and the second with positive identification.

Part I. Unidentified Cadavers

The issue of unidentified decedents is a large and underestimated one, also because of the lack of knowledge concerning the frequency of unknown decedents in different geographical contexts. Very few countries have a database for the comparison of missing persons and unidentified decedents, which is surprising, given the increase in legal and illegal immigration and a society with looser family and social ties and obligations. Hanzlick et al. published epidemiological data from Fulton County (Georgia) and created one of the first web sites with information and demographical data on unidentified decedents.

Very few indications are available in Europe, and in different countries, the precise number of unknown decedents is not recorded or still partially known; a recent study from Italy (a high immigration rate country) reported that at least 800 individuals are recorded as unidentified in medicolegal institutes. Similar orders of magnitude have been given for France by the press but official numbers do not exist. However, the real frequency of unknown decedents is likely to be higher than

reported, due to the occurrence of unrecorded immigrants and the lack of precise information on unidentified bodies in different institutes of legal medicine and morgues.

Identification in every case requires a comparison between antemortem information from the 'suspect' (the person who the remains may belong to) and postmortem data from the corpse; however, this comparison can be performed between profiles only if a possible match has been reached. And the possible match(es) is selected because it shows compatible characters, for example, such as sex, race, age, and stature, with those of the cadaver. Building up general data from remains is called 'general identification,' and the biological data extrapolated from the cadaver or human remains is the so-called 'biological profile.'

The biological profile consists of general characteristics of sex, age, race, and height of the individual and all individual markers that can be useful for identification (tattoos, scars, bone calluses, dental work, etc.). When the cadaver is in good condition, the pathologist can be independent in extrapolating all relevant information (although a toxicologist may be useful for detecting the presence of helpful (identification-wise) substances or medication in the blood or tissues). If the remains are badly preserved or skeletonized, then an anthropologist and odontologist may be useful. Most of the steps and diagnoses these disciplines, particularly anthropology, go through are discussed in the relevant articles. Briefly, when genitalia are not recognizable, sex can be easily defined by the analysis of the pelvis, and especially of the pubis, whereas cranial characteristics are less reliable; an accurate diagnosis can exceed 98% with the pelvis. In addition, the cranial features may suffer important modifications with time, as shown by masculinization usually reported in the crania of old females. On the other hand, osteological diagnosis of sex is difficult or even impossible to reach in case of subadults, where DNA must come in.

On the contrary, age estimation is easier in subadults than in adults, where it can be performed from the analysis of skeletal and dental development. The error of age estimation increases with age. In adults, age estimation can be linked only to degeneration processes. The main methods are Suchey-Brook's method on the pubic symphysis, Iscan's method on the fourth rib's osteochondral surface, and Lovejoy's method on the auricular surface of the ilium. Most commonly applied dental methods are Lamendin's and Kvaal-Solheim's methods. Ancestry determination in decomposed corpses can rely on the histological analysis of residual skin and hair, which show decisive differences between the main races. In skeletonized remains, the diagnosis of ancestry may be reached by morphological and metrical assessments of the cranium and postcranial bones. In addition, race determination may be performed by Fordisc software®, based on different cranial and postcranial measurements taken in American samples from different ancestries, although its adherence to the main racial groups is questionable. Stature is related to the length of long bones and can be determined also from fragmented bones by specific formulae, but in this case, the inaccuracy is high. A complete X-ray analysis is obligatory in order to verify the presence of bone traits (e.g., Harris lines, calluses), as well as dental traits (e.g., restorations), which can be useful. Finally, facial reconstruction should be performed provided investigators have the final 'identikit' circulate with the appropriate precautions:

facial reproductions may remind observers of a person who has been missing, but it may not necessarily bear a close resemblance.

Once the biological profile is complete, the obtained identikit should be compared with missing persons and/or circulate as much as possible in the hope that someone (investigators or the general public) may come up with a possible match for identity.

Part II. Personal Identification: Comparison between Antemortem and Postmortem Data

Once circumstantial evidence, comparison with missing persons or other investigative activities, have led to a suspicion of identity, personal identification is then based on the analysis of the specific and individualizing characteristics observed in the unknown decedent and their comparison with similar data from the matching 'suspect': every type of identification requires a comparison that must be founded on biological features. Positive identification may be reached by different methods. The first and most immediate for well-preserved cadavers is visual recognition of facial characteristics (e.g., with a photograph). The comparison may also be performed through fingerprints or genetic comparison if an adequate antemortem reference sample is available. In addition, since dental and skeletal features are unique, odontological and radiological methods may be applied with success if consistent antemortem material from the identity suspect can be obtained. Finally, superimposition methods (craniofacial and dental superimpositions) can be used when other procedures cannot be applied, although the significance of results is questionable and their importance is limited to specific cases.

Individual Markers

Specific descriptors such as tattoos, prostheses, nevi, and scars may be useful for identification and, therefore, should be described and photographed. For this reason, with decomposed and burnt remains, specific care must be taken to clean the skin surface, at times by scraping off the initial epidermal layer, in order to visualize scars, moles, and tattoos that may be hidden underneath soot and superficially burnt skin.

As for most morphological methods of comparison between antemortem and postmortem material, there is no consensus concerning how many descriptors are needed in order to reach a positive identification; literature recently has attempted at standardizing the frequency of specific human descriptors among the general population. This may give the first impulse for statistical evaluation of bodily markers. However, one should consider that every descriptor from a morphological point of view is unique, although it may be found in other individuals. For example, a surgical scar is likely to be useful for personal identification; however, other persons may have a similar marker in the same bodily area. Most of markers are highly individualizing, since their morphology is unique; for example, a thoracotomy follows a standard procedure, but the profile of the cut mark, the sutures, and manner of bone remodeling leads to a unique profile of the marker, which is different among individuals.

The following is a list of more specialized identification procedures that go beyond the pathologist's competence.

Facial Identification

In different countries, the main identification procedure consists of showing the corpse to the relatives or acquaintances who are requested to give a positive identification, although visual recognition is often influenced by the emotional status of the observers, who are perhaps often more prone to identify the corpse by clothes and personal belongings. At times, however, even though the cadaver is easily identifiable visually, no acquaintances seem to exist or can be contacted. At this point, comparison of facial traits with identity papers such as drivers' licenses can be requested.

Indeed, facial features may be of some help for personal identification through a scientific process, although their reliability still needs to be verified. How can two faces (antemortem photograph and the cadaver) be proven as belonging to the same person? In cases of personal identification of the living from video surveillance systems, for example, comparison and superimposition of facial features is commonly used. In these cases, the morphological features of two facial profiles are compared in order to point out possible differences that may lead to an exclusion or similarities that may justify an identification. However, many limits still affect such procedures, particularly the lack of a standardized manner of comparison between two images. Therefore, at the moment, the comparison of facial features may be useful only for an exclusion of identity, if gross and otherwise inexplicable discordances between the two facial profiles are found. In addition, one should consider that these methods have been tested for personal identification in the living, whereas at the moment there are no experimental studies concerning this topic in case of unknown decedents (Figure 1). A similar rationale can be used for other parts of the body, for example, venous and mole patterns, with the limitations stated above.

Fingerprint Analysis

Fingerprints are among the most individualizing features, since they are also different in homozygous twins and are usually recorded by qualified police personnel: in addition, literature shows that even in corpses radically compromised by

decomposition or charring processes, they can be recorded and used for identification, provided antemortem prints are available. In many counties, however, this is limited to individuals who have a criminal record. Databases such as AFIS (automated fingerprint identification system) have proven to be efficient for this purpose worldwide. The problem concerning the pathologist or forensic expert in general may be in extracting prints from dead bodies that have already undergone decomposition.

According to the specific alterations, fingerprints can be recovered by different procedures and treatments: when hands are mummified or charred, which implies a loss of liquids, fingerprints have to be softened and reinflated, for example, by alternate incubation in alcohol and sodium hydroxide solutions. Once the fingerprints are softened, they may be inflated by injection of saline solution. In case of carbonized hands, the fists are often clenched and, therefore, are better preserved from the heat; in this case, they should be accurately preserved and cleaned avoiding any further damage; then, the application of specific types of latex can be useful in recovering a print (Figure 2).

In case of putrefaction, the first procedure consists of stopping any further modification, which can be reached by hardening the skin in ethanol for a time between a few minutes and 1–2 h. Saponification causes flattening of the papillary crests, so before inking the fingerprints should be reinflated.

Several methods have been published for recovering prints from decomposed human remains. It is important to realize that even in a cadaver that seems badly preserved and beyond fingerprinting, these methods can give useful fingerprints.

DNA Testing

Genetic analysis is usually considered the main method of identification in the cases of unknown decedents and is undoubtedly the most popular one. In countries with DNA databases, this may be, indeed, the best way to a quick and reliable identification. Comparison of the DNA postmortem asset from the cadaver or human remains with the antemortem asset of a 'suspect' implies obtaining biological material that certainly contains DNA of that specific person from, for example, a toothbrush, a razor, or other personal belongings. It must be certain that they are not contaminated. DNA from close relatives can also be useful and easily obtained with a mouth swab.

Figure 1 Example of superimposition between a 3D scan of the cadaver (in yellow) and the 2D image of the antemortem photograph.

Figure 2 Phases of fingerprint reproduction from a mummified finger by application of a latex layer.

Nonetheless, sometimes the recovery of antemortem material may not be possible, for example, in cases where relatives are not present (this may occur for mass graves where the bodies are discovered decades after the massacre or in cases of vagrants or illegal immigrants). On the other hand, some postmortem substrates such as calcined tissues or dry bone may still be challenging for the geneticist since DNA extraction may not be banale. Furthermore, sometimes DNA testing may be longer and more expensive than other methods, for example, dental comparison.

Odontological Methods

Teeth are highly individualizing markers, thanks to anatomical uniqueness and modifications that may derive from therapeutic and pathological variables; these factors contribute to creating a unique profile, different from one individual to the other. In addition, teeth are resistant to many taphonomical agents and carbonization and can be easily analyzed for personal identification.

Antemortem data usually comes from the dentist who treated the person in life and may provide descriptions, casts and orthopantomographs, and other dental radiographs (Figure 3). In collecting antemortem material, one should always keep in mind that the dental asset may vary with time; therefore, clinical data sometimes may not be reliable, according to time lapse and treatment between when the data was created and death. This explains the difficulties encountered in cases of personal identification of subadults, which often undergo to frequent odontological treatments and are affected by growth, with consequent progressive modification of the odontological profile.

Teeth individualizing markers are not only in the oral cavity but also in the palatal rugae. Palatal rugae are irregular ridges of connective tissue across the front portion of the palate and are highly variable and stable with time, regardless of odontological treatment. Recent articles also show that radical modifications of the palate caused, for example, by rapid maxillary expansion do not appreciably modify the profile, which can still be used for identification. In addition, comparison of the palatal profile does not require specific skills, since the results do not seem to vary between observers with and without

odontological experience. The only condition for applying this method is the availability of an antemortem cast of the upper arch, which is usually taken before many odontological treatments.

Radiological Methods: Comparison of Bone Profiles

The morphology of bones can also be extremely useful, usually from antemortem radiological analyses; in addition, some radiological examinations are frequently performed on the general population, for example, chest X-rays, and the bones visible on these exams can be useful for identification. However, this osteological approach is based on the morphological assessment of bone structures; this means that the results will not be easily quantifiable, with clear limits in expressing the probability of positive identification. In fact, while most physiological, surgical and pathological bone features seem to be quite common as proven by the first studies concerning the analysis of frequencies of specific markers within the general population, the morphology of every bone is unique although difficult to fit in a numerical perspective. At the moment, very few bone districts have reached an adequate standardization from a statistical point of view and precise algorithms by which to identify; the comparison of frontal sinuses is the most reliable method of identification, since they are different even in homozygous twins, and their applicability is limited only by the low frequency of this cranial radiograph in the general population (Figure 4). Other attempts at the standardization of the comparison of other districts such as the thoracic vertebral margin are still experimental and need further studies.

Some authors have attempted at determining a minimum criteria for identification, which are stated in one to four unique analogous features without discrepancies, but a general agreement concerning this topic actually does not exist. There is no univocal and valid definition for the term 'unique'; therefore, the main difficulty consists of determining which feature may be considered unique and how many features are needed to reach an identification. In addition, since the comparison is based on a morphological evaluation, the matches and mismatches between the two profiles are often subjective and left to the personal opinion of the observer.

Figure 3 Odontological comparison by postmortem intraoral X-rays (defined by a colored line) and antemortem orthopantomography (OPT) in the background.

Figure 4 Example of superimposition of frontal sinuses between antemortem X-rays from the identity suspect (on the right) and the unknown decedent (on the left); frontal sinuses in the antemortem are in yellow and the postmortem in red; the results of the superimposition in orange.

Superimposition Methods

When none of the previously cited methods can be used, a last possibility lies in the superimposition of photos from the identity suspect and images of the cranium of the unknown decedent. This procedure, called craniofacial superimposition, cannot be used alone to reach a positive identification because of its low reliability. The main reasons consist of the difference between the two compared profiles (soft tissues and hard tissues); in addition, the results and success of this method of identification are highly variable according to different authors. At the moment, the only reliable use consists of excluding identity if gross incompatibilities are observed (Figure 5).

A similar procedure can be applied to dental profiles: if antemortem photos of the missing individual when smiling and showing his or her front teeth are available, a comparison can be performed by a superimposition of the dental elements visible in the photograph and those visible in a photograph of the cadaver or of a dental cast of the remains. In this case, the identification potential is greater because the method compares the same structures (teeth): one should only pay extreme caution to obtaining the same orientation and verifying that gross alterations of the teeth did not occur after the picture was taken.

Conclusions

An unidentified body may come in different conditions, ranging from well preserved to skeletonized or burnt. For this reason, the expert should be familiar with most methods of identification in order to choose the most reliable, cheapest, and fastest one for that specific case.

This survey is concluded with an outline summarizing, at present, possible solutions for performing positive identification of human remains by comparing antemortem and post-mortem data, with the relative advantages and disadvantages.

Well-Preserved Body

It should be stressed that it may be more difficult to compare a dead face with the picture of a living face in the attempt to declare that it is the same person. This is confirmed by the difficulties encountered by anthropologists dealing with

the identification of living individuals on photographic material (e.g., on video surveillance recordings of bank robberies, etc.). In these cases, it is necessary to compare the physiognomic traits of the person represented on tape or on a photograph with the face of the suspected thief or assailant. While this appears to be a banale and intuitively simple activity, it is anything but simple. Comparing the morphological and metric traits of two images for the purpose of arriving at a definite identification of the subject is still complex: this is due to the differences in orientation of the two images and to the lack of standardization of such procedures. In the same manner, in the case of a well-preserved cadaver to be compared with a photograph of a living person, serious problems in determining the traits that may be crucial for identification can turn up. It is for this reason that it is important to support a mere resemblance with specific descriptors such as scars, tattoos, moles, and so on.

Identification can obviously be performed by the methods suggested below.

Putrefied, Burnt, Partly, or Completely Skeletonized Human Remains

For this type of material, depending on which districts are better preserved, the following methods should be applied:

Significant descriptors: This is the case of putrefied bodies presenting countermarks (or features) so singular as that they may be used for identification purposes. Examples of these identification instruments are residues of tattoos, scars, bone prostheses or anomalies, unusual mutilations, and surgical operations.

Fingerprinting (dactyloscopy): It is always worth while trying to restore the papillary crests in order to be able to obtain sufficient dactyloscopic data for the comparison of fingerprints. This, however, presumes that the subject's prints were taken during his lifetime and that antemortem fingerprints of the subject are available.

Odontology: if a detailed antemortem dental chart, dental radiographs, or other clinical dental data exist, they can be used for comparison with the dentition of the human remains. Such data, however, must be available and the dentition of the remains fairly well preserved. The advantages of this method are its rapidity and low costs. One disadvantage, compared to

Figure 5 Example of craniofacial superimposition.

DNA analysis, could be the nonquantifiability of the result. For example, it is almost impossible to provide a judge with the numerical probability that two different individuals may share the same dentition. Many odontologists, however, feel that quantification of the result would be useless and that morphological methods are based on the operator's experience and common sense.

DNA: this is the most popular method and most expensive. It is necessary, nevertheless, to be able to extract the DNA from the remains, and in the case of dry bone, this can be difficult for the presence of polymerase chain reaction (PCR) inhibitors and degradation. Furthermore, there may exist no adequate relatives for DNA comparison or objects such as toothbrushes and combs from which to extract the individual's antemortem DNA may not be retrievable, as in the case of vagrants and illegal immigrants. The advantages of this method consist in being able to supply a quantitative result, owing to the studies on the distribution of the alleles of specific loci within a certain population, which makes it possible to provide the probability that another person shares the same genetic asset. Other possible setbacks may be that it is more expensive and requires more time.

Anthropology–Osteology: Image superimposition: These methods are used when the above described methods are not applicable. Superimposition can be dental or craniofacial. As already mentioned, dental superimposition requires the existence of a decent-quality photograph of the living subject, smiling, in order to be able to compare his or her dental profile with that of the human remains. Craniofacial superimposition, where craniometric points of the soft tissues are compared with craniometric points of the remains, is less reliable. These investigations require good quality photographs. In the case of dental superimposition, the methodology, although incapable of quantifying the error, at least compares the same structures.

Radiological comparison of frontal sinus shape or the morphological correspondence between the shape of any bone (e.g., vertebra) can be a valid method of identification, although one must be very cautious in matching the orientation of the antemortem and postmortem radiographs and in looking for sufficient corresponding traits.

In conclusion, results always need to be carefully examined by an experienced observer. Personal identification has to be carried out with a set of data, after having carefully evaluated the limits and the possible sources of error of each method.

Deaths in Custody

S Heide, University of Halle-Wittenberg, Halle, Germany

Introduction

The deaths of persons in police custody pose a particular challenge to postmortem and forensic assessments. These deaths typically generate substantial public and media interest, with law enforcement officers often blamed for the deaths. The media often cite a lack of medical independence in the assessment of the decedents' fitness for custody, as well as inadequate medical care while the decedents were in police custody. Reports of ill treatment by law enforcement officers, sometimes including torture, are not infrequent. Torture in police custody, sometimes with a fatal outcome, has been reported in Egypt, China, Nepal, Zimbabwe, South Africa, Bangladesh, Iran, Peru, Syria, Turkey, and Uganda.

The circumstances in which the death occurred and the range of possible causes of the death must be known in order to develop an objective expert assessment of deaths in police custody and to develop preventive strategies. For this purpose, the authors have completed systemic and significant studies of deaths in police custody from cases that occurred in North America, Australia, and Europe.

Frequency of Death in Police Custody

Throughout the world, there is a high risk of serious health hazards or death in police custody because arrested individuals are often intoxicated or were involved in physical conflicts just prior to arrest. Although determining the incidence of deaths in police custody requires a reference to the total number of police arrests, such figures are not available. Therefore, this study will relate the number of deaths to the population figure. Literature gives the frequency of such deaths as at least 0.1 per 100 000 citizens; however, the exact death rate varies considerably. A German study on death in police custody showed, at 0.14 per 100 000 citizens, that Germany has a relatively low death rate compared to similar countries. Significantly higher mortality rates in police custody were shown, for instance, for Finland (2.02 per 100 000 citizens), Canada (0.87 per 100 000 citizens), and Australia (0.89 per 100 000 citizens).

Distribution of Age and Gender

The majority of studies on death in police custody state that 90% of the persons who die in police custody are males. The low percentage of female deaths is due, primarily, to the fact that women are comparatively taken into custody less often. In Halle and Bremen, two large German towns, 90.5% of the 3669 persons in police custody were males.

Contrasting age distribution of persons who dies in police custody and the range of causes of death in police custody

shows considerable differences between North American and European deaths in custody. Because of the different structures of prisons and of custody (such as the length of time that a person may be held in police custody) in these regions, however, the studies are not fully comparable. National differences in the police and justice systems mean that, in Europe, deaths in police custody are not always distinguished from deaths in prisons. In a German study of 60 in-custody deaths that were followed by a postmortem, age distribution was widely spread, the mean age being 41.1 years (Figure 1). In contrast, deaths in custody in Denmark, Great Britain, Canada, and the Netherlands occurred in much younger persons. Men in Florida (USA) died mainly in their 40s or 50s. An awareness of these age distributions is of considerable importance for the medical assessment of a person's fitness for custody. The process of finding a person fit for custody must be the same for every person, even if the arrested person is of younger age.

Manner and Cause of Death

In the North American region, the proportion of natural deaths in police custody is significantly higher than in Europe. More than half of the 229 deaths in Florida (USA) had natural causes. In stark contrast, natural causes of death in Europe are only 20%. In European countries, causes of unnatural death are predominately intoxication and trauma. The German study found that alcoholic intoxication and cerebrocranial trauma were prevalent (Figure 2).

Other European countries show a similar pattern. In Finland and Denmark, the most frequent cause of death was acute alcoholic intoxication; in the Netherlands, the most common cause of death was intoxication by a variety of substances. In England and Wales (Great Britain), intoxication induced by alcohol or medical and illegal drugs was responsible for a third of all deaths. The number of deaths by trauma was smaller: the proportion of deaths caused by craniocerebral injuries in Europe, for instance, was largely between 10% and 20%.

In North American studies, the distribution of the cause of death differs significantly. In Florida (USA), for instance, heart and lung diseases, secondary diseases of alcohol consumption, and suicides were prevalent. The Florida data therefore rather corresponds to the causes of death observed in persons in the custody of European prisons, which are predominated by cardiovascular diseases and suicides by hanging.

An international comparison reveals that, compared to European countries, death of excited persons during police restraining and transport measures can be found more frequently in North America. This may be due to a greater frequency of drug intoxication (such as excited deliria influenced by cocaine) and different restraining techniques.

Figure 1 Age distribution of 60 deaths in German police custody.

Figure 2 Causes of death for the 60 deaths in German police custody.

Error Analysis for Deaths in Police Custody

Only few publications provide detailed information on the assessment of medical fitness for custody of persons who died shortly after being taken into custody. In Germany, the proportion of cases where the person had been assessed by a physician prior to his or her death was 38%; in the Netherlands, 42%; and in Denmark, 46%. The Dutch study found that, although medical examinations are conducted relatively frequently, the physicians' recommendations are not implemented. This failure is caused primarily because of the following: doctors underestimate the arrestees' degree of intoxication, doctors overlook arrestees' injuries, and police and doctors have difficulty communicating. For the 60 fatalities in Germany, the study identified an exact error analysis which also included the applicable legal basis (Table 1).

In medical assessment, diagnostic errors and the failure to admit arrestees' to the hospital were most frequent. In many cases, unconscious persons and persons with obviously serious head injuries, for instance, were left in custody after having been medically assessed. Considerable deficiencies in medical documentation or in monitoring recommendations were

also quite frequent. Even in cases where the person was unresponsive, for instance, physicians gave no monitoring recommendations whatsoever.

The police sometimes failed to consult physicians in cases where they were legally required to do so. Law enforcement also failed to conduct sufficient searches: in one case, the person placed in custody was insufficiently searched, enabling an arrestee to take a lethal dose of methadone. Deficiencies in the quantitative and qualitative mode of monitoring also occurred. The person's case history was sometimes insufficiently conveyed to the attending physician. For instance, police officers may fail to inform the doctor of an intake of numerous tablets, which witnesses had observed, or of a known case of binge drinking.

In 27% of the cases, however, retrospective analysis showed that death was very probably unavoidable even if the necessary diligence would have been applied. These include deaths caused by myocarditis, peritonitis, or coronary thrombosis where the persons did not express any typical complaints, neither before nor during their detention. There were also some suicides by hanging inside the cell although no one had noticed any psychological peculiarities before.

Table 1 Error analysis of the 60 fatalities in Germany

Area	Error frequency (%)	Typical errors
Medical assessment of fitness for custody	65	– Diagnostic error or failure to admit to hospital – Deficient orders to police officers – Deficient documentation
Police responsibility	55	– Failure to seek medical attention – Deficient qualitative mode of monitoring – Failure to observe monitoring intervals – Physician was given insufficient information on case history
Organizational deficiencies	17	– Admittance to hospital denied by paramedics or nurses

Forensic Assessment

In the assessment of whether officers of the police or a physician had violated their duty of due diligence, the estimation of the time of death is often of decisive importance. This is why in cases of death in police custody the corpse should, as a principle, always be forensically inspected *in situ*. This, unfortunately, is rarely the case.

When inspecting the corpse, the decedent's clothing and the cell must first be searched for packages of medication or drug utensils. Close attention should also be paid to potential conspicuous odors, the contents of the oral cavity (to identify, e.g., tablet residues, aspirated stomach contents, foreign bodies), or injection marks in atypical locations. In addition, the hairy and hairless scalp should be examined for injuries (swellings, abrasions, ecchymosis, or lacerated-contused wounds).

In cases of death in police custody, officers or physicians are often blamed after the fact. An objective assessment of such allegations requires the identification of the cause of death by a medicolegal autopsy. The result of a multinational survey, however, shows that this approach is not a matter of course. Although Germany claimed to be a role model in these matters – leading one to believe that all deaths in custody are subject to a postmortem examination – the German study on death in police custody found that, due to different legal regulations in individual German lands and a need to reduce costs, these postmortem exams did not always occur. By a visual inspection of the corpse alone, lethal intoxications of alcohol, drugs, or medical drugs – which account for 40–50% of all deaths in custody in Europe – cannot be diagnosed.

The forensic assessment of potential due diligence violations requires, besides the postmortem examination result, an identification of blood alcohol content, a chemical-toxicological analysis, current medical findings (if available), and information provided by witnesses on the person's condition before and during his or her detention. The assessment must also take applicable legal provisions on the treatment of persons in police custody into account. In Germany alone, the differences between the lands' custody ordinances and policing laws are considerable: for instance, rules for how an arrestee should be monitored by police personnel, or the procedure to be applied if a person is unfit for custody.

Criminal Prosecution in Cases of Death in Custody

Although many deaths in police custody could probably be avoided, the physicians and police officers involved rarely face criminal prosecution. Their risk to become subject to potential civil litigation, however, is somewhat larger.

An analysis of the criminal consequences of deaths in police custody in Germany showed that the sentences imposed were very moderate, because of the high requirements German law places on evidence. The analysis looked at 21 preliminary investigations against doctors, officers of the police, and paramedics. Three-quarters of the investigations were stopped because of insufficient suspicion, because the evidence did not prove with the required certainty that death had been caused by wrong conduct. In a case of lethal alcohol intoxication (BAC: 0.51%), the prosecution dropped the matter without asking for an expert report. According to them, the quantity of alcohol the person had drunk had not been noticeable to the doctor despite the fact that the man had already been unresponsive when examined for fitness for custody 4 h before.

There were only a few cases in which the prosecution took a stricter approach. In two of them, proceedings were dropped on conditions and, due to low culpability, both doctors had to pay a fine. In the first of these two cases, the physician had found a man fit for custody who had died of cerebrocranial trauma shortly afterward. Witnesses, however, had observed that the man had at first been unresponsive and had later complained of a headache. In the other case, involving lethal intoxication with alcohol and medical drugs, the physician had affirmed fitness for custody despite the fact that the person displayed strong symptoms of intoxication when he was examined.

The only noted conviction concerned a physician who was fined for having caused bodily injury by passive negligence. The physician declared fitness for a man who had to be carried into the cell and had a bruise on his head. The postmortem revealed that death had been caused by subdural hematoma, and the forensic expert report stated that surgical intervention would very probably have saved the man's life.

A Case History

A 38-year-old man was found helpless and unresponsive on the pavement by pedestrians. At the police station, he was

shown to a physician in order to assess his fitness for custody. The doctor did not note any neurological symptoms but described, among others, facial abrasions. He declared the man fit for custody and recommended hourly checks. An officer of the police described that the man's speech had been slurred during the examination and that he had been unable to get up on his own. Thereafter, the officers conducted only sporadic checks. Although the man's mind clouded increasingly, the officers abstained from consulting a physician again. The man died 14 h after having been brought to the station. The postmortem examination revealed that death had been caused by cerebrocranial trauma with fracture of the skull and epidural hemorrhage. The torso showed several hematomas up to a size of 15×6 cm and fractures of the 5th, 6th, 7th, and 8th left ribs. The blood alcohol content was 0.03%, meaning that the man had been clearly intoxicated at the time he was taken into custody. The chemical-toxicological analysis was negative.

The arresting officers were investigated for involuntary manslaughter or failure to lend assistance. The forensic expert report emphasized that the monitoring of the arrestee's mental state had been objectively inappropriate, both in terms of frequency and the monitoring measures applied. Nevertheless, the prosecution dropped the case. It was not possible to prove involuntary manslaughter because they were unable to prove with the certainty required by criminal law that medical intervention would have prevented death. The prosecution also regarded the evidence for failure to lend assistance as insufficient since the officers had believed that the man was sleeping it off.

The physician was also investigated, but the investigation was dropped because his description of the person's condition at the time of his assessment differed considerably from the account given by the officers. Thus, it was a case of his word against theirs and the principle of 'in dubio pro reo' had to be applied.

Prevention of Death in Custody

Medical care for persons in police custody is often seen as critical, not only by the general public but also in the specialized literature. Possible deficiencies are caused by unregulated medical responsibilities, a lack of assessment standards, and confusing legal provisions. The factors would be a good starting point to facilitate the prevention of death or of relevant health hazards in police custody.

The assessment for fitness for custody, which is an area of enormous responsibility, should be carried out by experienced and trained physicians. The range of physicians who assess fitness for custody is, however, on an international level, extremely heterogeneous. Depending on the legal bases and regional conditions, the aim should be to assign medical responsibility clearly. In Sweden, for instance, such assessments are given by specialists in forensic medicine; in the Netherlands, by medical officers of health. The lack of clear assignation in Germany, for instance, means that physicians often refuse to conduct such examinations. In these cases, the ministries and police authorities concerned have to try to enter into service agreements

with individual physicians or institutions, which can be problematic.

International standards or national guidelines for the examination of fitness for custody are currently widely missing. Opinions on requirements for these examinations vary from a short assessment or symptom-oriented statement over a standardized process, to an examination of the whole body. Written documentation of these examinations and the decision on fitness for custody is not always compulsory. Here, the aim should be to reach at least a national consensus. This would offer the chance to improve medical care in police custody and to formulate preventative strategies.

Examinations for the assessment of fitness for custody are often carried out in unfavorable conditions. Diagnostic means are commonly limited, and the examinees are often not particularly cooperative. However, even in such circumstances, physicians must exhibit due diligence. This requires calling an interpreter if the examinee speaks a different language, knowledge of legally prescribed monitoring modes, and written documentation of the arrestee's condition. Especially in problematic cases, a person should only be found fit on conditions (e.g., requirements and instructions on monitoring, instructions on intake of food and medical drugs, consultation of a specialist) in order to limit the extent of medical responsibility. Traumatized or clearly intoxicated persons in particular require checkups on their wakeability to spot a potential clouding of consciousness; these checkups must be defined by a physician if there are no respective legal provisions. Unconscious persons or persons whose consciousness is clearly clouded must be classified as medical emergencies and do not belong in the custody of the police.

In revising legal bases or formulating national guidelines, sufficient examination conditions and certain requirements for cells should also be stipulated. The assessment of fitness for custody has to be conducted in a sufficiently heated and lit room that provides the possibility to examine the person in a horizontal position. Bunks must be designed in a way that prevents dangerous falls. Cells should not contain any structures that would provide inmates with the opportunity to affix rope-like instruments for suicide attempts. Especially in cases of the arrest of a large number of persons, it will not always be possible to avoid multiple occupancy of a cell. But by introducing general video surveillance, potential conflicts between the occupants can be faster detected and addressed.

The high proportion of intoxications and trauma contributing or causing death in custody shows that persons with head injuries or clear alcohol- or drug-induced loss of functions must be seen by a physician. Literature, however, frequently reports that it is not always easy for police officers to get medical assistance when required. Nevertheless, medical examination must not be dispensed with, especially in problematic cases. Local police stations must have the opportunity to consult a doctor speedily even at night or on weekends.

Police officers must provide the attending physician with comprehensive information on details and history of the case. Observations, particularly on the intake of drugs, tablets, or binge drinking, must be passed on. Police monitoring of persons in custody must strictly comply with the legally prescribed

monitoring mode or the one recommended by the doctor. Police officers should be trained on what they have to pay attention to when making these checkups.

Central custody suits offer a good possibility for the optimization of monitoring and adequate response to potential health deterioration. In contrast to detention at a station, the staff working in these central facilities is not involved in any other duty and can therefore focus on the required checks and any consequent measures.

In approximately 10% of all arrests, the person is judged unfit for custody. The responsibility for the life and well-being of these persons, however, cannot be placed on medical laymen (e.g., police officers). Here, appropriate regional solutions such as central, medically monitored custody suites or agreements with hospitals must be provided.

Even if the utmost care is applied, not every death in custody can be avoided. But by taking suitable preventative measures, it will be possible to reduce the number of deaths and injuries in police custody considerably. The German study also showed that in a quarter of all cases, death was likely unavoidable even if due diligence had been applied. Other countries have had similar experiences.

The systematic analysis of death in police custody can provide concrete indications for preventative measures. The Netherlands has a special analyses structure, designed for use by the police; however, this structure is probably not feasible for every country. It is, however, absolutely necessary to subject all persons who die in police custody to postmortem examination, because only an objective postmortem result will allow dealing with allegations of blame and developing preventive strategies.

Suicide*

M Große Perdekamp, S Pollak, and A Thierauf, University of Freiburg, Freiburg, Germany

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Copycat act Imitating the act of another person.

Dissimulation Hiding one's intention under a feigned appearance.

Murder-suicide Killing another person before committing suicide.

Introduction

The term 'suicide' refers to the intentional taking of one's own life. A suicidal act can either be uncompleted (attempted suicide) or can result in death (completed suicide). Although there are no reliable statistical data on the incidence of suicide attempts, it is assumed that their number is several times that of completed suicides. Nonfatal suicide attempts are predominantly committed by females. Even if some of these acts suggest that they are rather suicidal gestures or cries for help and that death is not really intended, such acts also have to be taken seriously – last but not least because the attempt may be repeated with the risk of an uncalculated fatal outcome. In fact, evidence of previous suicide attempts (e.g., scars from wrist cuts) is often found on persons who took their own lives.

Epidemiology

All around the world, suicide is a frequent manner of death. According to the WHO, every year almost one million people die by suicide. The global incidence indicated for 1 year is 16 per 100 000 people. Furthermore, the WHO reports that in the last 45 years, suicide rates have increased by 60%.

In different regions of the world, there is a wide range of methods of suicide. In mainly agricultural areas, particularly in developing countries, intoxications by pesticides are among the leading ways of suicide. Worldwide, approximately one-third of all suicides are caused by pesticide self-poisoning. Up to 40% of all suicides on the Indian subcontinent and the Middle East are committed by self-immolation. Easy access to firearms facilitates their use also for suicides. For instance, they account for about 60% of suicides in the United States. In Central and Western Europe, the most common methods are hanging (Figure 1), death by firearms, falls from height, intoxication, drowning, and collisions with rail vehicles (Figure 2).

Suicide is one of the alternatives of 'unnatural death.' According to medicolegal definition, the manner of death is

classified as unnatural if a fatality was brought about by suicide, accident, criminal action, or some other external effect.

In view of the wide range of the subject, only some forensic aspects can be addressed here. Therefore, this article concentrates on the diagnosis of completed suicide and its differentiation from homicide.

Fundamentals and Definitions

Possible Reasons and Dispositions

'Balance-sheet suicide' is defined as taking one's own life after thoroughly considering one's personal situation and perspectives. In practice, it often remains doubtful whether suicides were really committed voluntarily, that is, after making a calculated, rational decision, or whether external reasons (e.g., a personal crisis) or psychopathological dispositions may have led to the development of suicidal thoughts and impulses.

High-risk groups are patients suffering from depression and schizophrenia, drug and alcohol addicts, lonely and uprooted persons, as well as individuals with suicidal crises or suicide attempts in their history. There are also cases in which individuals unexpectedly kill themselves in a mental blackout (e.g., after a seemingly trivial dispute or because their driving license was withdrawn).

Complex Suicides

The criminalistic and medicolegal evaluation of suicides can be difficult if two or more suicide methods were applied simultaneously or rapidly one after the other within one and the same act. Such cases are called 'complex suicides' and can be divided into primary (planned) or secondary (unplanned, improvised) forms. For 'secondary complex suicide,' it was also suggested to use the term 'protracted suicide.'

In primary (planned) complex suicides, the fatal outcome is to be guaranteed by deliberately using two or more mutually accelerating methods (such as infliction of a gunshot injury together with hanging, see Figure 3). A secondary (unplanned) complex suicide is defined as one in which the first method fails, turns out to be unexpectedly painful, or does not cause death quickly enough, so that the individual spontaneously switches to a different method (e.g., superficial wrist cuts in the first phase followed by hanging to complete the act). Recently, the existence of still another subgroup has been demonstrated. These cases are characterized by a failure of the chosen suicide

*Parts of this chapter were published as a scientific article in Forensic Science, Medicine and Pathology (Medicolegal evaluation of suicidal deaths exemplified by the situation in Germany, Forensic Science, Medicine, and Pathology, 2010, Volume 6, Number 1, pages 58–70, Markus Große Perdekamp, Stefan Pollak, and Annette Thierauf). The material is used with kind permission of Springer Science+Business Media.

Figure 1 Suicidal hanging of a young man with the knees bent and the feet touching the floor. The hanging device was a belt forming an open noose fixed to the handle of a window. The blinds had been pulled down to prevent early detection of the victim. A suicide note was found on the desk.

Figure 3 Complex suicide by an angled contact shot to the right temple and consecutive hanging. The weapon used was a small caliber rifle (0.22 Ir). The noose was fixed to a water pipe mounted on the ceiling of a cellar room. The periorbital hematoma was caused by gunshot fractures of the anterior cranial fossa. The man had suffered from depression and insomnia.

Figure 2 Frontal aspect of a train after collision with a 63-year-old woman who remained standing between the rails in an upright position in spite of warning signals. The back was penetrated by a hook so that the body was carried along until the train came to a standstill. Death was caused by blunt cranial trauma with exenteration of the brain.

method so that the victim would normally survive. Owing to special circumstances at the scene, an unintentional secondary trauma (e.g., fall from a height after breaking of a noose) causes the victim's death. This constellation was defined as a separate entity called complicated suicide.

Suicide Pacts

The term 'dyadic suicide' (double suicide or suicide pact) refers to cases in which two or more individuals mutually agree to die together and either kill themselves or agree to be killed by their partner. This type of suicide has some common characteristics:

- Simultaneous or directly consecutive suicide/homicide acts
- Application of the same suicide method
- Act committed at the same place (typically in the apartment)
- Intimate (mostly heterosexual) relationship between the persons involved
- Serious physical illness as the predominant motive for committing suicide

Murder–Suicide

The term ‘murder–suicide’ (homicide–suicide) refers to the case of an individual intending to commit suicide, which includes at least one person into the killing act without the latter’s agreement or against the latter’s will; in most cases, there is a close relationship between the persons involved (family members, sexual partner). As mentioned above, this group does not include dyadic suicide in which the partner has agreed to be killed. The same applies to suicides committed after a homicide – so to speak as a reaction to it – and essentially determined by feelings of remorse, guilt, and fear of punishment. An important factor of homicide–suicide is the rapid chronological order of homicide and suicide. Most male perpetrators kill with the help of firearms, less often by means of manual/ligature strangulation or sharp force; preferential methods for the subsequent suicide are shooting and hanging. In most cases, homicide and suicide are committed at the same place or near to it. Perpetrators with pseudo-altruistic motives may show ‘undoing’ behavior (e.g., ‘posing’ of the victim, decoration of the scene with flowers, pictures, and candles).

Occupation-Related Suicide

Often forensic experts are confronted with occupation-related suicides. It is quite understandable that persons with special vocational skills, experiences, or knowledge will also apply these when committing suicide. In addition, in some fields of activity, potential suicidal tools not available to others are readily accessible. Well-known examples are suicides using firearms by persons allowed to carry guns (police officers,

soldiers, hunters, sports marksmen), the use of livestock stunners by butchers, slaughterhouse workers, and farmers, as well as the suicidal use of explosives by blasters.

A pilot may take his life by wilfully crashing the aircraft. Physicians and other health care professionals mostly commit suicide by taking drugs orally or parenterally; another occupation-related mode is the painless infliction of cut wounds with a scalpel after applying a local anesthetic. The method used can also be related to the special anatomical/postoperative situation of a patient (e.g., transection of a shunt placed for hemodialysis).

Lethal cyanide poisoning is particularly often seen in chemists, jewelers, and metal workers. In farmers and horticulturists, toxic pesticides may be used for committing suicide by poisoning, which is sometimes indicated by a characteristic smell or warning dye (Figure 4). Electricians sometimes construct special devices with timers to electrocute themselves while they are asleep.

Dissimulation

Both attempted and completed suicides can be subsequently disguised. The motives for covering up the true facts are manifold. In the past, religious reasons and the wish for a church burial may have been of importance. Even today, the surviving partner may sometimes be afraid of being held responsible by the suicide’s family, especially if the relationship was full of conflict. There are even cases in which a suicide victim stages an act similar to a homicide so that the survivors will receive the full amount of his life insurance.

Suicidal gunshot injuries are sometimes inflicted such that they resemble an accident (shot allegedly triggered unintentionally

Figure 4 Poisoning with methiocarb (mercaptodimethur), a carbamate-type pesticide. Red liquid covers the skin around the mouth (a). It also discolored the stomach contents (b) and the gastric mucosa (c). The suicide victim was an 80-year-old woman who had suffered from dyspnea and severe pain due to osteoporosis.

during the hunt or while cleaning the firearm). The same applies to self-killings in road traffic, which are difficult or impossible to distinguish from genuine accidents without special circumstances (e.g., previous announcement of suicide, additional self-inflicted injuries within the definition of a complex suicide). After incomplete suicidal acts, the suicide sometimes pretends to have become the victim of a criminal offense.

Examples for (attempted) dissimulation of a suicide by family members are removal of a hanging device and application of a chin strap before calling the doctor for the post-mortem examination; change of the situation at the scene, for example, by removing evidence pointing to suicide such as a suicide note, empty drug packages or a drinking glass; removal of a plastic bag pulled over the head. This has to be distinguished from wrong postmortem diagnoses made by the examiner without being consciously or intentionally misled.

Of particular medicolegal relevance are cases disguised as a suicide in order to cover up a homicide. In the literature, it has been pointed out again and again that a firearm found in the victim's hand may have been placed there to simulate suicide. However, the number of homicides covered up in this way is very small. On the other hand, there are many proven suicides in which the weapon was found in the suicide's hand after firing the shot. In homicides, superficial cuts on the forearms or neck may create the impression of tentative or hesitation cuts thus simulating a suicide – independent of whether this was intended by the perpetrator or not. When a severely traumatized body is found near railway tracks, homicide (e.g., by shooting) with subsequent simulation of a railway accident or suicide has to be taken into consideration.

A particularly important category, which is not sufficiently discussed in the Anglo-American literature, comprises alleged suicides by hanging, which are actually homicides. Basically, two procedures have to be distinguished:

1. The victim is killed by hanging or
2. Subsequent hanging of the victim injured or killed before by some other method (e.g., blows, manual, or ligature strangulation)

Copycat Acts

Already Goethe's novel 'The Sorrows of Young Werther' showed that suicidal acts reported by the media can prompt copycat acts in emotionally labile persons. Serious journalists therefore take care to avoid excessive detail about the method used in their reports. A well-known example that press reports can actually prompt copycat acts is the massive increase of suicidal self-suffocations by means of plastic bags pulled over the head, after the publication of the book 'Final Exit: The Practicalities of Self-Deliverance and Assisted Suicide for the Dying' by Derek Humphry (New York). In medicolegal practice, copycat acts are seen not only in connection with suicides and homicides but also in fictitious criminal offenses.

Criminalistically Relevant Phenomena and Suicide Scenes

The incidence of different suicide methods depends on temporal, cultural, and regional influences. Societal change is also

reflected in the availability of certain means of suicide, for which carbon monoxide poisoning is an excellent example: Town gas, which played a major role as a source of poisoning in the twentieth century, has long been replaced by natural gas, which does not contain carbon monoxide. Until the 1990s, nonaccidental carbon monoxide intoxications were mostly brought about by conducting exhaust fumes into the interior of a car, but nowadays this method has lost its former importance due to the common use of catalytic converters in automobiles. At present, an increasing number of suicidal carbon monoxide poisonings is due to charcoal fires in closed spaces.

A similar change can also be observed with other poisons formerly used for committing suicide: arsenic poisoning verified by autopsy has drastically declined just as intoxications by caustic and topically irritating agents such as acids, lyes, certain metal salts, phenol and its derivatives, which were frequently seen before the Second World War. In the 1950s and 1960s, E 605 (parathion), an insecticide belonging to the substance class of phosphorous acid esters, was so commonly used for committing suicide or poison murders that there was really an 'E 605 fashion.' Even the spectrum of drug intoxications has changed in the more recent past (decrease of barbiturate intoxications, increased use of tricyclic antidepressants, neuroleptics (Figure 5), and parenterally administered insulin preparations as a means to commit suicide). Nowadays,

Figure 5 Suicide by ingestion of psychotropic drugs (antidepressants and neuroleptics). About 70 tablets had been mixed with some water (a). At autopsy, the stomach still contained a large amount of the paste-like material (b). The victim was a 55-year-old woman who suffered from depression and had made several suicide attempts before.

suggestions for 'new' suicide methods are often obtained from the Internet, such as suffocation by breathing a helium-enriched atmosphere.

A suicide locality that has become increasingly popular for about three decades is the bathtub. Apart from traditional forms (cuts to the wrists or the neck, stab wounds to the heart), the number of suicides combining an overdose of drugs or alcohol with subsequent drowning in the bath water is increasing. Electrocution in the bathtub, a method of suicide mostly chosen by women, presents significant diagnostic problems, as very often there are no electrothermal skin lesions. Deaths due to electric shock in the bathroom always raise the possibility of an accident or a homicide.

Regional differences in the frequency distribution of the methods of suicide are partially attributable to special construction features and means of transportation: Thus, suicides in the underground railway can occur only in metropolitan areas; suicides by falls from height are seen not only in cities with multiple-story houses but also in places with high stand-alone buildings such as viaducts, high bridges, viewing towers, or at deep precipices (cliffs, steep rock walls). Near natural bodies of water such as rivers, ponds, or lakes, drowning is a preferred method of suicide, which can even be reflected in local expressions used for announcing a suicide ('to go into the water'). In rural areas, where hunting weapons are common, it goes without saying that these are also often used for suicide ('to put a bullet through one's head').

Suicide Under the Influence of Alcohol and/or Drugs

A high percentage of suicides are committed under the influence of alcohol. The largest number of intoxicated victims is found in the third-to-fifth decade of life. In connection with suicidal acts, a moderate amount of alcohol consumption is also called a courage dose.

Consumers of illicit drugs may kill themselves out of despair over their personal circumstances or under the influence of withdrawal symptoms. It is difficult or even impossible to distinguish overdoses with an unintended fatal outcome from intentional suicidal acts, unless the external circumstances (announcement, suicide note, etc.) provide hints in this respect. As in suicides by an overdose of medicine, one has to bear in mind that suspicious utensils may have been removed by flatmates or family members before the post-mortem examiner sees the deceased. Quite often, drug victims are taken to another place and dumped there to hide their actual place of death and make police investigations in the drug scene more difficult.

Certain illicit drugs with psychedelic effects such as LSD, mescaline, and psilocybine intensify emotional experiences and sensory perceptions, cause illusions and hallucinations or change the orientation as to place, time, and person; occasionally, they may cause feelings of omnipotence followed by fatal trauma (e.g., by jumping from a height under the impression of being able to fly).

Suicide in Road Traffic

As most cars are now equipped with catalytic converters, the number of suicides by conducting exhaust fumes into the

interior of the car or in a closed garage with the engine running has decreased. Another method is that the suicide intentionally causes a fatal pseudo accident. It is estimated that at least 1% of the traumatic deaths occurring in road traffic (without pedestrians) have a suicidal background. Certainly, there is a considerable number of undetected cases, as in single-vehicle accidents often no autopsy is performed and no technical opinion is obtained.

Suicide in road traffic always has to be suspected if a vehicle is driven at high speed against a solid object, into an oncoming truck, deep water, or a precipice for no apparent external reason and without a reaction of the driver. Clues pointing to suicide may be a suicide note, announcements of suicide, economic and personal problems, and the absence of braking or skid marks. The forensic literature contains numerous reports on very unusual forms of killing oneself with the help of a motor vehicle (for instance, a suicidal gunshot to the head while driving a car). Under differential diagnostic aspects, suicides committed in or with motor vehicles have to be differentiated not only from genuine traffic accidents, but also from natural deaths at the steering wheel and homicides (with attempted disguise by staging a pseudo traffic accident).

Suicide in Hospitals, in Police Custody or Prisons

It is estimated that about 3% of all suicides are committed by hospital patients. About half of these are inmates of psychiatric institutions (mainly patients suffering from schizophrenic psychoses or endogenous depression). Among nonpsychiatric patients, those with malignancies play a major role. Preferred methods of suicide are jumping from a height (e.g., from an upper floor window or balcony, see [Figure 6](#)) or hanging.

Suicides in police custody, pre-trial detention, and prison constitute a special category. The peak age of this group – composed almost exclusively of males – is reached in the third decade of life. Several studies arrived at the conclusion that suicides are particularly frequent during pre-trial detention and at the beginning of the prison term. Hanging is the preferred method with objects available in the cell such as bed sheets or clothes being used as ligatures. The noose is fixed, for example, at the bolt of the window, a bar of the window grill or a heating pipe. Less often, suicidal intoxications or completed suicides due to sharp force are observed. Every death in prison or police custody requires an autopsy in which not only suicides, accident-related traumata (sub- or epidural hematomas), and injuries inflicted by another party, but also natural causes of death (such as ischemic heart disease, myocarditis) are detected.

Suicide by Drowning

Genuine or alleged suicides in the water are a challenge for the examiner, even when excluding the above-mentioned deaths in the bathtub. Suicides in the bathtub and in natural bodies of water are predominantly committed by women. Especially after a prolonged postmortem interval, it is difficult to distinguish between suicide, accident, homicide, and death from a natural cause. Tying is seen both in suicides and homicides; the same applies to weights (stones, dumbbells, etc.) used to make a body heavier and prevent it from surfacing. Sometimes the

Figure 6 Scene of suicide. The victim was a 57-year-old psychiatric inpatient who had left her ward unnoticed and jumped from an outside staircase of the hospital (height about 20 m).

presence of tentative cuts or stabs suggests a (secondary complex) suicide. Concomitant injuries sustained by falling into the water, hitting obstacles, or drifting along a stream of flowing water can make it even more difficult to differentiate between suicide, homicide, and accident. Most suicide victims drowning themselves in the open air are fully clothed. Many of them are significantly intoxicated.

Self-cremation

Compared to former centuries, the number of suicidal self-cremations has increased. While in the 1960s and 1970s self-incineration was a means of political protest and prompted copycat acts, most suicidal acts nowadays do not seem to have a political or religious background, at least in the Western countries. The number of psychotic patients is particularly high. In the majority of cases, a fire accelerant (petrol, spirit, turpentine, etc.) is used. The victims have often attempted suicide before. Burns are typically more pronounced on the upper half of the body than on the lower extremities. This seems attributable to an initially upright posture. The COHb concentration can be very low even with clearly vital burns; COHb values above 30% are rare. Self-incineration can be combined with other suicide methods such as stab or cut wounds, jumping from a height, gunshot injuries, or hanging.

Medicolegally, differentiation between accident-related burns, self-cremation, fire homicides, and homicidal fire deaths is of prime importance. Homicides by burning ('fire homicides') are either committed by directly setting the victim on fire or by setting fire to a building/vehicle with the intent to

kill. This must be distinguished from 'homicidal fire deaths,' which refers to premeditated murder with the subsequent attempt to cover up the traces of the crime and to eliminate the victim as far as possible by starting a fire.

Strangulation

Death by hanging is often too readily associated with suicide. Although accidental self-hanging (e.g., of children or in connection with autoerotic practices) is known among experts, it can be overlooked by postmortem examiners, particularly if the situation at the scene is not obvious, or was subsequently changed.

The opinion that hanging by another person is possible only if there is a significant disproportion between the strength of the perpetrator and the victim or if the victim is impaired in his/her ability to act (e.g., by alcohol or drugs), is not absolutely true. Clues pointing to homicide are, for example, injuries on the neck (additional ligature mark, fingernail abrasions, bruising), traumatization of other body regions not related to the hanging, signs of a fight or drag marks, suspicious situation at the scene (free suspension without something to step on, distance between the neck and the suspension point too short, grooves caused by pulling up the body).

Differentiation between suicidal and homicidal ligature strangulation may also involve significant diagnostic problems. In addition to general medicolegal aspects (no evidence of forced entry, a suicide note, no evidence of a struggle), the following findings may suggest self-strangulation: no other

neck injuries away from the ligature mark, no evidence of previous physical overpowering, no defense injuries, ligature positioned tightly around the neck. Several ligatures and/or complex knots or the use of a gag do not exclude self-strangulation; the same applies to hairs or jewelry caught between the neck and the noose. The additional presence of tentative incisions supports the assumption of (secondary complex) suicide. Signs of congestion are particularly pronounced in self-strangulation (facial congestion, cyanosis, petechial hemorrhages above the strangulation level). On the other hand, the skin mark discernible after removing the ligature can be very inconspicuous. Fractures of the laryngeal structures are very rare in self-strangulation.

Sharp Force

Sharp force injuries are much more frequent in suicide attempts than in completed suicides. Suicidal stab wounds are predominantly localized in the precordial region (Figure 7). The number of wounds can vary greatly (from a singular stab wound to the chest up to more than 100 individual wounds). Often further injuries by sharp force (wrist and/or neck cuts) are found. Typical morphological criteria for self-infliction are: localization in the cardiac region, lesions largely parallel and arranged in groups, presence of shallow hesitation cuts, combination with tentative cuts and absence of defense injuries.

While some older textbooks describe perforation of the clothing as a clear sign of injury inflicted by another person, it is now generally accepted that the 'rule' of exposing the chest before suicide has many exceptions. Especially in psychotic patients, perforation of the clothes is by no means rare.

The tool used is not only found near the corpse but can also be lodged in the body or – provided that the ability to act was maintained long enough – may even have been removed by the suicide victim himself/herself. Occasionally, suicidal stabs are also located in the cervical area (Figure 8), the upper abdomen, the inguinal region, or the arms. Highly atypical suicidal acts (e.g., stab to the nape of the neck) may be difficult to differentiate from homicides.

The above criteria also apply to the differentiation between suicide and homicide in victims with cut wounds. Sites of predilection for suicidal cuts are the front of the distal forearms and the neck (Figure 9). Apart from 'classical' constellations of findings with a multitude of equally shallow tentative cuts arranged in parallel, there are also exceptional suicides with only one deep cut severing the tissue. Here, several extensions in the corner of the wound may indicate that the blade was repeatedly moved backward and forward. Both on the forearms and the neck, cuts may run either in a transverse or a diagonal direction. Some suicide victims even inflict cuts along the longitudinal axis of the arm. In about half of all suicides with wrist cuts, these are localized on both forearms. In other cases, they are typically located on the side opposite to the dominant hand (i.e., mostly on the left). In suicidal cuts to the neck, the clothing usually remains undamaged.

Firearm Injuries

Experience has shown that the medical evaluation of gunshot injuries is particularly prone to misinterpretation – last but not least because of the great variability and complexity of gunshot findings, which even experts sometimes find difficult to

Figure 7 Suicide by sharp force (42-year-old man addicted to alcohol and illicit drugs). Multiple stabs to the cardiac region and tentative lesions in the precordial and upper abdominal region (a). Superficial cuts on both arms running parallel to the longitudinal axis (b). At the scene, two kitchen knives with blood-stained blades were found (c).

Figure 8 Complex suicide by sharp force and ingestion of drugs (48-year-old woman who had suffered from depression). Three superficial stabs to the left side of the neck (a). One deep and several shallow cuts to the right wrist (b). The victim was found in the open air and a suicide note was detected in her car parked near the scene.

interpret. In view of the large variety of suicidal gunshot wounds, the criteria described in the following can only be an approximate guide.

Localization of the gunshot entrance wound

Regions considered typical of suicide are the temple (more often on the right than on the left, no strict correlation with the dominant hand), the mouth (intraoral shot), the cardiac region (in four of five suicidal shots to the chest the area is not bared), the forehead, and the submental region ('shots to the floor of the mouth'). If long guns are used, shots to the temple are less common and shots to the chest are more frequent than with handguns. Livestock stunners are mostly applied to the forehead – as with animals to be slaughtered. Wounds in the upper abdominal region are mostly regarded as 'misdirected shots to the heart.'

Atypical suicidal gunshot entrance sites are the occiput, the nape of the neck, and the parietal region, although in suicides committed with a slaughterer's gun the latter is often chosen as the preferred site. Occasionally, gunshots into the ear or eye are observed.

Firing distance

Suicidal shots are usually fired with the muzzle pressed against the skin. For this reason, they normally show the characteristics of a contact shot (powder cavity, muzzle mark, and sometimes stellate skin laceration), unless they are intraoral shots. Interposed textiles may modify the findings, especially in shots to the chest, and cause external soot soiling around the entrance

wound in spite of the close contact between the muzzle and the body. External soot deposits are also possible in near/loose or incomplete contact shots or angled contact (e.g., [Figure 3](#)). Suicidal shots from a larger distance are possible when special devices are used (e.g., fixation of the weapon in a vice, triggering the shot with a string).

Number of hits and bullet track direction

In questionable suicides with more than one gunshot wound, it must be decided whether after the primary injury the suicide victim could have retained or regained the ability to act. If this is so, suicide victims with two or more gunshot wounds to the chest (or the adjacent abdominal region), to the head, or to the chest and the head are possible. Continued ability to act after a gunshot wound to the brain may occur if low-energy ammunition has been used and/or the bullet track avoided the 'targets of immediate incapacitation'; in most of these cases, the projectile hits either only the frontal lobe or one of the temporal lobes. Further causes of suicidal multiple gunshot injuries are initial self-infliction of graze shots or shots to the limbs, use of automatic weapons, simultaneous firing of two weapons or two barrels, the occurrence of tandem projectiles (a bullet stuck in the barrel is expelled by the next one) and unintended double shots due to a technical defect of the disconnector.

The question as to whether a bullet track is compatible with a self-inflicted gunshot wound cannot be generally answered, but depends on the weapon used (long gun or handgun), the

Figure 9 Suicide of a 53-year-old woman who inflicted cuts to both sides of her neck and to the flexor sides of her forearms. As only minor vessels had been severed, the victim survived for a prolonged time and finally died from hypothermia due to the low outside temperature. The cuts were inflicted with a scalpel found close to the body. The rear end of the incision on the right side of the neck (a, b) showed some shallow notches indicating that the blade had been moved back and forth several times. The skin of the precordial region displayed superficial tentative lesions (c). Another three cuts were located on the flexor side of left forearm (d). The woman had a history of paranoid psychosis and several suicide attempts.

way in which the weapon was held, the position of the body and the way in which the trigger was pulled.

Findings on the hands

Quite often suicides use both hands: the firing hand proper (with the index finger or thumb at the trigger) and the supporting hand, with which the barrel is positioned and held (mostly by grasping it around the barrel end). In any case, careful preservation and documentation of all findings on the firing hand is of utmost importance. As to the technical methods for performing this kind of examinations and

the interpretation of the results, reference must be made to the relevant special literature. Traces of blood droplets and tissue particles flung backward ('backspatter') may be found on the firing hand of a suicide. Lesions due to the slide moving back are a rarity.

Road Traffic

Epidemiology

Traffic accidents are a very common cause of injury or even death (one of the leading causes of death in young adults) and as such are of high forensic relevance. The vast majority of deaths and injuries result from road traffic. In 2009, the number of accident victims and injured persons exceeded 33 000 and 2 200 000 in the United States; in the European Union, more than 35 000 persons died and 1 700 000 sustained non-fatal injuries in traffic accidents. WHO reports that approximately 1 300 000 people die each year worldwide and another 20–50 million are injured. According to the WHO statistics, low-income and middle-income countries have significantly higher road traffic fatality rates than high-income countries (the fatality rate in high-income countries is approximately 10 per 100 000 persons, in low-income countries twice as much).

Of the above-reported US fatalities, 72% were car occupants (52% drivers and 20% passengers), 13% motorcyclists, 12% pedestrian, and 2% cyclists; similar percentages have been reported in Europe. According to WHO estimates, the proportion of vulnerable road users among the fatalities is higher in low-income countries, so that globally almost half of those who die in road traffic crashes are pedestrians, cyclists, or riders – motorized two-wheelers. The numbers of fatalities are decreasing in most industrialized countries continuously. In most regions of the world, the epidemic of road traffic injuries is still increasing.

Relevant Injury Types

Accident investigation is a very complex interdisciplinary work aiming at the reconstruction of time history of parameters related to the movement and interactions of vehicles and persons immediately before and during an accident. Injuries constitute very important traces. The routine clinical documentation would typically be insufficient because some minor, and thus for the treatment irrelevant injuries, would potentially not be accounted for. For this reason, a thorough body inspection (in nonfatal injured) or an autopsy by a forensic pathologist is to be performed in order to assess the injuries and collect other traces (small parts from vehicle, etc.) from the body. Care must be taken regarding the anthropometric data – basic body measures as well as the exact locations of all injuries must be ascertained and documented. Apart from descriptions and photographs, computed tomographies (CTs), 3D-scans, and other methods can be employed for injury documentation. In accident investigation, the skin and bone injuries are the most important because they carry the most information about the interaction between the human body and its surroundings. Apart from injuries, an analysis of the clothing is to be performed (though not necessarily by the pathologist).

There are two types of information an injury analysis can offer – injuries enable inferences regarding the injury mechanism, that is, the art of loading, and regarding the amount of loading. Thus, based on injury analysis, the investigator can reason back as to the particular cause. The immediate injury cause is always the force acting in the injured tissue. However, there is not always a clear topographic relationship between the external force acting on the surface of the human body and the injury location; injuries might occur in distant body regions because of force transmission. An example – indirect rib fractures caused by thorax compression – is shown in [Figure 1](#).

Skin injuries

Abrasions – superficial skin injuries resulting from tangentially inflicted force (scraping along the body surface). Its direction can be established based on the morphology (bevel descent at the beginning and a tag consisting of accumulated epidermis at the end). The shape of the injury gives clues about the size of the contacting object; sometimes a pattern can be found that reflects some of its morphology.

Stretch injury – if the skin is stretched beyond its elasticity, injury occurs along the cleavage lines (defined by the natural orientation of collagen fibers). If the skin was stretched as a result of extensive movement of body segments, the injury shows in typical locations over protruding bony structures; such injuries give clues about the segmental movements during the accident. An example is shown in [Figure 2](#).

Hematoma – soft tissue bleedings resulting from blood vessel damage. Depending on the size of the blood vessel and the surrounding soft tissue structure, even serious blood loss affecting the hemodynamics might occur. Hematoma shows on the skin typically only after a lag of several hours or days. Its resorption takes up to several weeks and is accompanied by color changes that might help an experienced investigator to narrow down its time of origin. Typically, its shape reflects initially the morphology of the contacting object, and in the course of time, it changes as the blood follows the cleavages in the soft tissue, the muscle fasciae, and so on. Tire profile might leave negative impression on the skin (see [Figure 3](#)).

Decollement – separation of the subcutis from the underlying fascia as a result of tangential blunt force imposed on the affected body part, accompanied by a formation of a wound cavity that might be filled with blood (see [Figure 4](#)). This injury type results typically from being ran over by a car tire or from a primary contact between a pedestrian and a car. The overlaying skin is frequently intact; sometimes tire marks can be observed.

Laceration – apart from incisions (cuts), open wounds can result from compression, shearing, and/or tensile force, that is, from blunt force. The edges of the wound might be ragged, bruised, or abraded and thus potentially giving hints as to the contacting object. Sometimes bridging strands (blood vessels, nerves, tissue strands) can be found especially in the deeper

Figure 1 Direct (left) and indirect (right) rib fractures; the former as a result of an interaction with an object in the location of the fracture, the latter as a result of chest compression in the anterior–posterior direction (the ribs brake on the side, i.e., not at the contact location).

Figure 2 Typical stretch injury of the skin in the groin caused by extensive extension of the left hip (pedestrian accident victim).

Figure 3 Tire profile marks on the skin of the right arm of an accident victim.

layers. The shape of the wound can help to identify the contacting object.

Head injuries

Traumatic brain injuries

Traumatic brain injuries (TBIs) are mechanical insults to the brain associated with temporary or permanent impairment of brain function. The distinguishing mark of TBI is an altered state of consciousness.

Figure 4 Wound cavity filled with blood developed as a result of direct blunt trauma (primary impact of a pedestrian hit by a passenger car).

From a clinical point of view, TBIs are classified by using the Glasgow Coma Scale (GCS) of the patient shortly after the traumatic incident:

Mild TBI: $13 \leq \text{GCS} \leq 15$

Moderate TBI: $9 \leq \text{GCS} \leq 12$

Severe TBI: $\text{GCS} \leq 8$

The GCS quantifies the conscious state of a patient based on his/her eyes (eyes do not open – 1 point; eyes open in response to pain – 2 points, eyes open in response to voice – 3 points, eyes open spontaneously – 4 points), verbal (no sound – 1 point, incomprehensible sound – 2 points, inappropriate words – 3 points, confused verbal statements – 4 points, normal conversation – 5 points), and motor (no movements – 1 point, extension in response to pain – 2 points, abnormal flexion in response to pain – 3 points, flexion/withdrawal in response to pain – 4 points, localization of pain – 5 points, obeying of commands – 6 points) responses.

The traditional and still widely used classification based on the morphology differentiates also three degrees:

1. *Commotio cerebri* (concussion) – a temporary and reversible impairment of brain function (diagnostic criteria: loss of consciousness, amnesia, nausea/vomit, headache)
2. *Contusio cerebri* (brain contusion) – a distinct injury of the brain tissue (cerebral contusion, intracranial bleeding)
3. *Compressio cerebri* (brain compression) – this grade is characterized by an increased intracranial pressure caused by brain swelling and/or intracranial bleeding; since the cranial cavity is not deformable, the only direction the brain can expand is toward the foramen magnum and that is where the brain can be clamped. Secondary bleedings especially in the pons area might follow leading to severe brain damage or even death

Intracranial hemorrhages

Intracranial hemorrhages are bleedings inside of the cranial cavity. According to their localization, they can be divided into following types:

Epidural hematoma – a bleeding between the skull bone and the dura mater. The bleedings are caused by damage to one of the meningeal arteries, typically as a result of skull fracture.

Subdural hematoma – a bleeding between the dura mater and the arachnoidea caused by damage to one or more of the bridging veins, typically in incidents with high head acceleration

Subarachnoid hematoma – a bleeding between the arachnoidea and the pia mater, caused typically by damage to small brain arteries.

Intracerebral hematoma – bleeding within the brain tissue typically caused by damage to small blood vessels in the convolutions of the brain.

In head impacts with high linear acceleration of the head, focal brain injuries can occur not only directly underneath the impact site, but also on the opposite side of the brain (inertia of the brain and its interaction with the skull being the assumed cause). The hemorrhage areas on the impact side (coup, see Figure 5) are typically less pronounced than on the opposite side (contre-coup). High rotational accelerations typically lead to diffuse injuries of the brain tissue (DAI=diffuse axonal injuries).

A striking finding after head trauma are raccoon eyes (unilateral or bilateral) – a periorbital hematoma (bruising around the eyes). Its presence is strongly suggestive of skull base fracture (and not of blunt force acting in the eye region).

Thorax injuries

Heart contusion (contusio cordis) – occurs in blunt chest traumata and can lead to cardiac arrhythmia.

Lung contusion – because of contusions and bruises of lung tissue, the gas exchange might be impaired and/or blood might enter the respiratory tract leading potentially to death through suffocation.

Pneumothorax – if due to an open thorax injury air gets into the pleural cavity (between the lungs and the chest wall), the negative pressure is neutralized and one or both lungs might collapse. Sometimes a ventril mechanism forms that allows air to flow to the pleural cavity but prevents its escape (the so called tension pneumothorax); the state of the injured might deteriorate rapidly and lead to death within a short period of time. Also an accumulation of blood in the pleural cavity (hemothorax) might lead to breathing and/or heart action impairment. A combination of both (air and blood in the chest cavity) is the hemopneumothorax.

Flail chest – although simple rib fractures per se do not constitute a relevant danger, serial fractures in various locations can lead to a detachment of a part of the rib cage that

moves (due to the pressure within the thorax) opposite to the rest of the chest (paradoxical breathing movement). This constitutes a life-threatening injury. Sharp rib fragments in displaced fractures might cause lung lacerations with (hemo) pneumothorax.

Aortic rupture – tears of the chest aorta are rarely the result of direct force (although sometimes seen in overrun accidents). Typically the aortic rupture is caused by high accelerations (e.g., an impact of a nonbelted driver on the steering wheel).

Diaphragm rupture – can occur in car occupants as well as in pedestrian as a result of an impact. It is a relatively rare finding, but the fatality rate is high.

Pelvic injuries are of high clinical importance because they can be associated with severe bleeding. Fractures of the pelvic ring are typical for side collisions, whereas acetabulum fractures occur primarily due to femoral shaft axial loading, that is, due to force transfer from the knee/foot region in frontal collisions. This mechanism can also lead to posterior dislocations of the hip.

Abdominal injuries

Abdominal injuries result typically from blunt force and can be associated with very high danger to life. Perforations of the digestive system lead to infections and inflammations of the abdominal membrane (peritonitis).

Injuries to the extremities

Fractures of long bones

For accident reconstruction, fractures of long bones, especially of the legs, are of a great importance. Relevant are both the localization and the shape of the fracture. The latter enables to distinguish among torsion fractures, compression fractures due to axial loading of the bone, and bending fractures. All kinds of fractures can be observed in traffic accidents. In bending fractures, the direction of force can be reconstructed – if a bone is bent beyond its tolerance, it starts to fail on the tension side and the fracture lines typically form a wedge pointing in the direction of the acting force (see Figure 6). Complicated fracture patterns might be very difficult to interpret.

Car Occupants

Injuries of the car occupants are frequently the most important traces that enable to reconstruct their position in the car (driver vs passenger). Apart from injuries (among the most important

Figure 5 The coup and contre-coup injuries.

Figure 6 Wedge-shaped bending fracture of long bones, the apex of the wedge showing the direction of the acting force.

Figure 7 Seat belt injury, car occupant in severe frontal crash; the shoulder belt consistent with the driver position in the car (in left-hand drive vehicles).

Figure 8 Superficial skin injury caused by shattered glass (right upper arm of a car occupant); the long and deep cut was made by a pathologist.

are seat belt injuries – **Figure 7**; injuries caused by pedals, airbag injuries, and injuries from glass fragments – **Figure 8**), a thorough inspection of the car interior (contact locations, possibly with biological traces) must be performed. Since airbags deploy not until the crash, the existence of biological (DNA) traces is strong evidence regarding seating order. Another question that can be clarified by a thorough injury analysis (in combination with other methods) is the seat belt use. In multiphase accidents, the assignment of injuries to individual events (interactions) might be very tricky.

Frontal collisions

Seat belt injuries – occur as a result of the interaction between the restrained occupant and the (typically three-point) belt. In severe crashes, bony injury (ribs, clavicles, and sternum, fractures typically located along the belt contact site) can be found as well as abdominal wall disruptions and mesenteric tears. The typical seat belt sign – a skin abrasion running diagonally across the chest (shoulder belt) and/or across the lower abdomen (lap belt) – can show in an impressive way (see **Figure 7**) or not at all; sometimes, subcutaneous bleeding along the belt line can be found in the autopsy in spite of no visible trauma sign on the body surface. A missing seat belt injury does not necessarily imply that the belt was not used (e.g., the belt might have been rolled out because of precrash movements of the occupant). For the same reason, knee (and/or hip and/or pelvic) injuries as well as head injuries might occur in spite of seat belt use.

Airbag injuries – the interaction with the airbag can lead to face, skull and/or jaw fractures, teeth luxations, eye injuries, burns, or hearing damage. Depending on the hand location at impact, injuries of the hand and/or lower arm might occur (fractures, burns, etc.). Injuries might be caused by eyeglasses, pipes, and other objects between the face and the inflating bag.

Side collisions

With respect to a particular occupant, far-side and near-side (struck side) impact should be distinguished. An impact to the side of the vehicle, where the occupant sits, leads to direct loading via blunt force (the injuries result from cabin intrusion as well as its acceleration). Typically, the impact side of the head, the thorax, and the pelvis are affected. Seat belts are not effective in near side impacts, and so seat belt injuries are not likely to occur. The injuries of occupants on the struck side are typically more severe than on the far side of the vehicle.

In far-side collisions, the torso of the occupants might slip out of the shoulder belt and severe head injuries can occur

(interaction of the head with the dashboard, the near-side occupant, or the intruding far-side cabin structures). The upper body of the occupant stays impinged by the belt and the excessive belt loading might lead to abdomen injuries including typical belt signs on the skin.

Rear-end collisions

Low-impact rear-end collisions are being frequently investigated because of whiplash-associated disorders (WADs). Severe crashes might lead to cervical spine injuries (fractures, dislocations) and/or head injuries.

Rollover collisions

The loading imposed on occupants in rollover crashes is variable. Isolated rollovers are rare and belted occupants frequently suffer only minor injuries in spite of extensive car damage. Severe injuries typically occur due to occupant ejection (possible in spite of belt usage if the seat collapses) or due car impact secondary to rollover; in the latter case, the injury patterns resemble those of frontal, side, or rear-end collisions depending on the impact direction. Severe blunt head trauma and/or compression cervical spine injuries occur as a result of roof crush.

Whiplash-Associated Disorders

Nonphysiological movements in the cervical spine region can cause significant disorders ranging from discomfort to neurological symptoms and/or injuries to the bones or ligaments. In Europe, more than one million car occupants report to suffer from WAD after a car crash, the costs are estimated to be between 5 and 10 billion EUR. In the United States, more than one million people are affected every year and the costs are approximately 30 billion dollars. The WADs are typically classified according to the recommendation of the Quebec task force (QTF):

Grade 0	No symptoms No physical signs
Grade 1	Symptoms such as pain, stiffness, or tenderness No physical signs

Grade 2	Symptoms such as in Grade 1 Musculoskeletal signs such as decreased range of movement and point tenderness
Grade 3	Symptoms such as in Grade 1 Musculoskeletal signs such as in Grade 2 Neurological signs such as decreased or absent deep tendon reflexes, muscle weakness, and sensory deficits
Grade 4	Symptoms such as in Grade 1 Fracture or dislocation or spinal cord injury

The exact injury mechanism is not known; microlesions of soft tissue caused by combined translational and rotational movements of spine segments are frequently hypothesized. In traffic accidents, the torso is typically accelerated through the seat; as a result of inertia, a complex relative movement between the head and the torso including both traction and bending of the cervical spine follows. **Figure 9** shows typical spine kinematics during a rear-end collision – due to a force imposed by the seat back, the thoracic spine flattens and at the junction to the cervical segments, a vertical force component occurs (thoracic ramping); simultaneously, a retraction of the lower cervical spine can be observed. An extension of the cervical spine follows that is limited by the head restraint. Due to contact elasticity, the head as well as the torso typically rebound, which leads to protraction of the cervical spine. The forward movement of the torso is restrained by the seat belt so that a flexion of both upper thoracic and cervical spine follows. As a reference parameter for the amount of load imposed to the passengers, the collision-induced velocity change has been established. Because the collision duration lies typically in a tight range (0.1–0.15 s), the velocity change is proportional to the mean acceleration of the vehicle during the collision. Since the biomechanical tolerance limits were established based on the result of volunteer tests under controlled conditions, care must be taken that the value of the velocity change in the location of the person of interest is reconstructed (due to rotations, the velocity change in different locations of the car varies). The approximate reference values that result from various volunteer studies cannot be generalized as they refer to standardized (lab) situations. The assessment must always take

Figure 9 Typical spine kinematics during a rear-end collision. The wide arrows represent the external forces acting on the body, the fine arrows the movement direction.

into account the particular situation (especially deviations from the setup of the volunteer studies) and the individual parameters of the person. The most important factors influencing the injury outcome are the posture (especially of the head), the seat (and headrest) adjustment, degenerative or other pre-existing alterations, or injuries of the cervical spine, and so on.

Pedestrian Collisions

The interaction between a pedestrian and a car have typically the form of an impact, that is, the pedestrian is hit in an upright position by the car front. Runover collisions (without former impact) are much less common, but they may be of high forensic relevance (drunken pedestrian lying on the road vs camouflage of a homicide vs suicide). The injury outcome is dependent on the pedestrian kinematics, which can typically be divided into the following phases:

1. Primary impact – the contact between the pedestrian body and the car; typically, the lower legs are impacted by the bumper first and the hip and head impacts follow as the pedestrian body wraps around the car (the distance between the road surface and the head impact location measured along the car contour is called WAD = wrap around distance). In box-shaped cars (or in rear-end collision with station wagons, etc.), the impact of the leg, hip, thorax, and head regions can occur simultaneously.
2. Secondary impact – the contact of the pedestrian to the road (impact, sliding, and rolling). The distance between the point of collision and the end position of the pedestrian after the secondary impact is called throw distance; this parameter is frequently used for the collision speed estimation.
3. Tertiary impact – the contact between the pedestrian and the surrounding structures (another car, a tree, also a run-over counts as tertiary impact).

The pedestrian kinematics and thus the injury pattern depend to a high degree on the relationship between his/her anthropometry and the geometry of the impacting car. Several different kinematics types can be discerned – wrap kinematics (the pedestrian upper body wraps around the front hood/windshield and after the head impact, he stays on the hood or slides off to the ground), forward projection (the pedestrian is projected forward, typical for box-shaped vehicles or children), fender vault (the pedestrian first wraps around the hood and then exits off the side of the vehicle front), roof vault (the pedestrian wraps around the hood and his legs rotate further upward so that he is lifted), and somersault kinematics (the pedestrian upper body wraps around the car front, after the head impact, the pedestrian is flipped into the air as he continues to rotate). Another collision type is a sideswipe, that is, a movement of a pedestrian along the side of a moving vehicle; in such cases, the pedestrian might twist (rotate about his longitudinal axis) and suffer leg injuries on one side and head injuries on the other side of the body, both resulting from contact to the car.

The most important are the injuries that are able to reconstruct the impact direction – apart from fractures of the long bones of the lower and/or upper leg, the soft tissue findings (contusions, wound caverns, etc.) are of high relevance. Sometimes ankle and/or knee injuries help to reason back as to the

impact direction (supination vs pronation vs flexion vs extension in the joint due to impact, etc.). Only very rough estimation of collision speed based on the injuries is possible (and always to be performed also with the knowledge of the car damage); lower-leg fractures can occur even in collisions with a speed of less than 10 km h^{-1} , multiple rib series fractures and/or severe TBIs require typically collision speeds of above 30 km h^{-1} , and amputations of body segments above 80 km h^{-1} (unless the body part gets stuck in a car structure). The assignment of the injuries to individual contacts during a multiphase accident might be very difficult due to overlapping of injury outcomes. Runover leads sometimes to tire profile marks on the skin (that can appear as textile pattern due to clothing), massive soft tissue injuries with décollement is to be expected.

Two-Wheelers

Typically, the most serious injuries of riders are caused by impacts – with the own vehicle (e.g., pelvic ring fractures due to impact on the tank), with other vehicles, road infrastructure (guard railing), and other objects (a tree, etc.). For the accident reconstruction, compression injuries of the hands/lower arms due to handlebar grip are important (e.g., to differentiate the driver and the passenger) as well as superficial injuries morphologically attributable to contacting objects (vehicle parts, etc.).

Helmet injuries – wearing of a helmet at the time of an accident can result in skin abrasions underneath the chin strap or impression mark of parts of the visor. An example of helm injuries is shown in Figure 10. In severe crashes, helmets cannot prevent skull fractures and/or brain damage.

In bicycle collisions, severe injuries to the head occur especially if the cyclist does not use helmet and a car is involved. For accident reconstruction, injuries in the upper leg/pelvis region due to the interaction with the bicycle seat might be important (e.g., to clarify whether the cyclist was riding or pushing the bicycle).

Severe or even lethal injuries result also from a collision between a cyclist and a pedestrian. Fatal injuries are rare and result typically from the secondary fall of the pedestrian with

Figure 10 Typical helm injuries (motorcyclist, frontal collision with a passenger car); the helmet was found several meters away from the body, but its damage and the injuries prove it had been worn at the time of accident.

head impact on the road. For accident reconstruction, a characteristic wound on the lower leg of the pedestrian caused by the contact with the front wheel is the most important injury (though typically minor).

Railway

In 2009, 1391 people were killed and another 1350 were seriously injured in railway accidents in the European Union (European railway agency data). The total number of deaths is much higher, because the statistics do not include suicides (2719 in 2009, i.e., more than twice the number of accidental deaths). The number of deaths among railway passengers is very low; within the EU, only 196 persons died in the 3-year period 2007–2009. The US statistics reported 492 deaths and 5264 nonfatal injuries in 2011 (Federal Railroad Administration).

The most important factor determining injury severity in railway accidents is the huge mass of the vehicles. Injuries may be caused by an impact (pedestrian going/running/standing, car occupant), run over (pedestrian lying on the track, with or without contact to the wheels of the train), or dragging along by the train (a person or a whole car). In rare cases, persons fall out of a moving train, also known are deaths and serious injuries resulting from 'train surfing' (riding on the outside of a moving train). The differentiation between a suicide and an accident (or a homicide) can be very difficult; in suicide cases, the person lies typically on the abdomen across the rail so that the head or the upper part of the torso are severed by the wheels.

Air Traffic

The number of air accident victims is low and shows irregularities because of the very few events that lead to fatalities – in

2008, there were 170 fatalities reported in the EU, 154 hereof caused by a single major crash. In the United States, there were 30 accidents reported that cost 757 lives in 2009 (Aviation safety network).

In plane crashes, fatal injuries typically result from severe impacts; carbon monoxide or cyanide intoxication is also possible. In crashes into the water, the ultimate cause of death might be drowning.

Glossary

Identification Process of assigning a preexisting individual's identity and name to a corpse by different means of forensic sciences.

Mass disaster Man-made or natural incident with more fatalities than the local resources can handle; some sources declare incidents involving more than 100 victims as a mass disaster.

Definition

Generally, a mass fatality is described as a man-made or natural incident with more fatalities than the local resources can handle. As important infrastructures such as rescue and treatment services may be damaged, a certain dependency on the character and locality of the incident is obvious. Events of the last decade show the great variety of scenarios influencing the possibilities and requirements for forensic pathology:

- 2000 Cable car disaster – Kaprun, Austria – 155 victims
- 2001 World Trade Center – USA – 3000 victims
- 2002 Refugee – Ferry Le Joola – Gambia – 1863 victims
- 2003 Explosion gas-mine – Chuandongbei – 191 victims
- 2004 Tsunami – Thailand and Indonesia – 230 000 victims estimated
- 2005 Train crash – Amagasaki, Japan – 107 victims
- 2006 Car ferry – Dhiba, Saudi Arabia – 1026 victims
- 2007 Bomb attack – Bhutto's parade, Pakistan – 135 victims
- 2008 Plane crash-Spanair – Madrid, Spain – 154 victims
- 2009 Air France Flight 447 – Rio de Janeiro to Paris, Brazil – 228 victims
- 2010 Earthquake – Haiti – 200 000 victims estimated
- 2011 Tsunami and reactor disaster – Fukushima, Japan – 20 000 victims

The identification of the victims is the main objective of forensic efforts related to mass disasters. Criminalistic reconstruction is very important too, but the consequences of missing identifications seem to be greater for the bereaved than the lack of information concerning the reason of the incident. Knight describes some reasons for identification efforts:

- Ethical and humanitarian need to know which individual has died, especially for the information of surviving relatives.
- To establish the fact of death with respect to particular individuals for official, statistical, and legal purposes.
- To record their identity for administrative and ceremonial purposes with respect to burial or cremation.
- To discharge legal claims and obligations in relation to property, estate, and debts.
- To prove claims for life insurance contracts, survivor's pensions, and other financial matters.
- To allow legal investigations, inquests, and other tribunals, such as those held by coroners, procurators fiscal, medical

examiners, judges, and accident enquiries to proceed with accurate information about the identity of the decedent.

- To facilitate police enquiries into overtly criminal or suspicious deaths, as the identity of the deceased person could be a vital factor for investigations.

Comparable to the great variability of the different scenarios listed earlier, there are great differences in the ways of handling identification problems. Information concerning all forensic efforts are not regularly published in the forensic literature or in political statements. Full autopsies were performed in the Kaprun cable car disaster (156 victims) (Figures 1 and 2) but not in the Eschede train disaster in 1998 that claimed 101 victims. Identification in these incidents was mainly based on molecular genetic investigations. The tsunami in Thailand in 2004 resulted in ~230 000 victims. Only a very small part of the fatalities was handled according to the Interpol identification recommendations (predominantly European victims in the main tourist areas). The major part of the German victims was identified by forensic odontology. Due to severe decomposition of the dead bodies, molecular genetic methods played a secondary role. A completely different situation was encountered in the World Trade Center terrorist attack in which identification without DNA-based methods was inconceivable. The airplane accident involving the Air France Flight in 2007 resulted in a majority of missing person cases with a few victims recovered some years later. As for the Haiti earthquake in 2010, which claimed ~200 000 lives, no information regarding a global identification effort has been reported. The identification procedures after the Fukushima disaster have also been awkward to handle, published forensic measures being very scarce.

In general, it can be ascertained that a high number of victims in a less developed area results in a lack of forensic identification activities. Contrary to this, a smaller number of victims (particularly from regions in Europe, the United States, or other highly industrialized states) in an incident happening in a highly developed area, leads to intensive forensic procedures executed over a long period of time (more than 1 year in the Thailand tsunami tourist areas).

Usually, forensic pathologists are embedded in disaster victim identification (DVI) teams, which have been constituted in most countries and which consist of a number of different specialists to cover the majority of possible situations. DVI teams have been established following different problems in

Figure 1 Obsequies, Kaprun disaster, Austria, 2000. Source: Prof. Dr. E. Tutsch-Bauer, Department of Forensic Medicine, Salzburg University.

Figure 2 Scene before recovery of the bodies, Kaprun disaster, Austria, 2000. Source: Prof. Dr. E. Tutsch-Bauer, Department of Forensic Medicine, Salzburg University.

the identification of mass disaster victims in the 1960s and 1970s. They are mostly governmental organizations, but recently, private companies have also begun to offer comparable services.

After an incident, the initial chaotic phase is usually followed by organization and acquisition of responsibilities by the different departments in charge. Typically, the police is the leading authority, but cooperation with experts in different fields is also sought. Incident management implies the establishment of command structures, emergency systems, law enforcement operations, family assistance, media operations, and logistical support, as well as financial and administrative support. A competent incident management requires experience and authority. The forensic pathologist can be a valuable

advisor concerning all decisions belonging to the recovery and identification procedures.

The complexity and character of the operations depend necessarily on the specific situation and mainly on the estimated number of fatalities and the condition of the bodies. Also, responder protection has to be considered according to the individual nature of the incident.

Airplane crashes and major fires may be the most frequently emerging problems for the forensic pathologist in this field. In crashes involving light planes, the number of bodies is small and the identification procedure that much easier. In crashes involving big commercial aircraft, especially in collisions occurring at a flying altitude of more than 30 000 ft (9000 m), grave problems can be expected with the number of

dismembered bodies being high. DNA analysis will play a decisive role in these incidents.

In all kinds of accidents involving means of transportation, investigations concerning evidence of explosion should be carried out.

In all kinds of accidents involving means of transportation, investigations concerning evidence for explosion should be made. Nowadays, the first question is the differentiation between an accident due to a technical defect (possibly resulting in civil action) and a terrorist attack. Also, the examination of victims, for example, for evidence of fire or bomb residue, may prove helpful.

Besides the passengers, there is a special interest concerning the pilot or the train driver. These victims require a full autopsy with a screening for diseases, signs of intoxication, or trauma not related to death. All cases in which a mistake on the part of the personnel is discussed as the reason for the crash, a detailed knowledge of any impairment of health is essential for all further deliberations. Prior to this of course is the identification of the pilot or other staff members from individual criteria and personal effects (dress code). Also, special injury patterns such as severe hand or foot injuries in a pilot may be helpful for identification; however, with the modern technology in airplanes, this kind of injury-dependent identification has lost its relevance in most cases.

Very important are all kinds of natural disease which may lead to an individual mistake as a reason for an accident: predominantly all kinds of heart disease, especially typical coronary atherosclerosis leading to a myocardial infarction, but also neuromuscular diseases or hypoxic changes in the central nervous system leading possibly to unconsciousness are to be discussed. Another aspect may be an impairment of a pilot due to alcohol consumption or intoxication with legal or illegal drugs. For this reason, analysis of blood alcohol concentration and toxicology are indispensable in all investigations concerning airplane crashes or train accidents.

Eisenmenger reported one case of a helicopter crash, in which the pilot was found intoxicated with a BAC of 2.3 g%. There were also reports on airplane crashes where the pilot was found with a lethal gunshot injury or a stab wound, obviously having been killed by one of the passengers in the context of a homicide-suicide event.

Tasks

The main tasks involving activities of forensic pathologists are:

- Recovery of the bodies at the scene.
- Disaster victim identification.
- Assistance in criminalistic incident reconstruction.

Recovery of the Bodies at the Scene

In the scenario of a mass disaster, the forensic pathologist is an auxiliary force working in line with the police after rescue operations have been terminated. The recovery of the bodies from the scene is an important step in successful catastrophe management. Not only in airplane crashes but also in other mass incidents, severe fragmentation of the bodies may be one

of the main problems. The forensic pathologist's opinion and an anatomic classification of the body fragments, as well as the differentiation between human and animal tissue, will be helpful. This applies accordingly to exhumations from mass graves and major fire accidents. A compartmentation of the scene in different sectors with the establishment of a grid system is usually a police exercise. The same applies to the documentation of bodies or body fragments, concerning the place of discovery and personal effects.

Tags should be applied to the bodies or body bags to ensure a continuous flow of the case file. The body has to pass through the different morgue stations (see below), and all the data have to be documented and compared afterward. Up to the final report and the release of the body, the case file and the identification form have to be signed by the leading police officer, the authorized forensic pathologist, and dentist.

Disaster Victim Identification

Identification is the main task of the forensic pathologist. The necessity for identification results from different laws. Inheritance is usually connected to the declaration of death of a person. The same applies to the payment from insurance companies, the possibility of a new marriage, and so on. Identification may result from different measures and is basically a duty of the police. One possibility often used in countries without a functioning forensic system is the ascertainment of identity by inspection of human remains by means of visual recognition. Also, a comparison with photographs is sometimes used for identification. In case of severe traumatic damage or decomposition of the bodies, this procedure is not feasible. However, even in cases with well-preserved bodies, erroneous identification has been reported, obviously very difficult situation for relatives or loved ones. For this reason, other methods for identification must be preferred.

Personal effects

Personal effects are items from victims' pockets, clothing, ID papers, or jewelry. The value for identification usually is limited to single items with an outstanding individual character. A certain commingling of all these items may happen due to events prior to the incident as well as by the catastrophe itself. However, important is also the return of personal items to the relatives and families of the victims. Special police units usually arrange for recovery, processing, and handing over of personal effects. In the Kosovo Identification Project, individual clothing was the main factor for identification success.

Fingerprinting

Fingerprints are very useful for identification as well as footprints and palm prints. Fingerprint experts are a part of all DVI teams. If possible, all opportunities should be taken to get fingerprint evidence processed by forensic experts belonging to the police. Finger, foot, and palm prints can be compared with prints taken from the assumed person's home or objects, which can be assigned to a certain person. Sometimes, this can be difficult and the assignment may be doubtful. Comparative prints may be missing (e.g., in a plane crash in a residential zone; after destruction of the accommodations, it will usually be impossible to get comparative prints). In some countries,

fingerprints are part of identity papers. Sometimes, a police investigation with a documentation of fingerprints years ago can be helpful. Nowadays, computer processing of all the evidence is possible, facilitating comparison in cases with large numbers of individuals.

Fingerprinting becomes less important in cases of severe fragmentation of the bodies or in major fires. Amputation of fingers or hands for fingerprint or palm processing at the fingerprint station as was commonly recommended in the past should be avoided because commingling is possible afterward and control of the results becomes more difficult.

Autopsy

Depending on the local factors, setting up of a temporary morgue might be necessary. Additional resources (staff, equipment, etc.) are required to perform autopsies, but the results of a forensic autopsy are essential for a complete identification procedure and for control purposes. The autopsy may be limited to special findings or procedures according to the condition of the bodies and the needs of identification. The main findings are related to gender, age estimation, body height, race, and individual markers such as tattoos, scars, results of a medical treatment, or malformations.

Gender determination: Depending on the condition of the bodies, primary or secondary sex organs may be detectable; body hair may be shaved; for skeletonized individuals, molecular genetics is an option.

Age estimation: Will cover only the biological age, not the actual age. Degenerative changes in the ankles or the spine may help as well as the degree of atherosclerosis and abrasion in the dental state.

Race: Determination of race will be impossible in cases of major fire and severe decomposition. Comparable effects occurred after the Southeast Asian tsunami in 2004 within a few days so that a differentiation between the local Asian people and Caucasian tourists was not possible any more.

Body constitution and nutritional status: May be difficult or impossible to assess in cases of fragmentation, burn injuries, and decomposition.

The report of the forensic pathologist should (if possible or determinable) contain the following information: body number, condition of the body, weight of the remains, missing body parts, gender, height, diagram of injury pattern, foreign bodies, hair color and length, eye color, scars and tattoos, birthmarks or other typical features, operations and prostheses, diseases, and x-rays or photographs of important findings.

The value of the findings depends on the condition of the body and the number of individuals who have to be identified. In cases of severe decomposition, fragmentation, or mass grave exhumation, the help of a forensic anthropologist is necessary. If the victims are skeletonized, special discriminant analyses can be helpful even if they are very complex. Prostheses and implants, as well as artificial lenses, radiological seeds, or pacemakers may offer a quick, simple, and safe means of identification of single individuals. An autopsy also offer the possibility to retain body fluids for further investigations (DNA, alcohol, toxicology) and to find some evidence concerning the cause of death or items such as projectiles, bomb fragments, or other injuries important for the criminalistic reconstruction. Interpol forms for antemortem and

postmortem investigations offer the possibility for an exhaustive data collection and a safe comparison of the findings even when supported by computer technology. However, in a number of mass disasters, only a small portion of the individual parameters can be collected as the Interpol forms require. In this situation, priorities have to be established.

In general, two possible ways can be discussed for identification: The first one is a systematic comparison between all antemortem and postmortem data, after all the operations have been completed. The second one is the selective identification and release of single bodies in a good condition with characteristic identity features and a stepwise narrowing of the group of unknown individuals. Additionally, a classification in different age groups or concerning gender may be helpful. In incidents involving a large number of victims and cooperation between DVI teams of different nationalities, a systematic approach is mandatory.

Forensic odontology

DVI requires support of experienced forensic odontologists. Teeth are very resistant concerning physical influences. Especially in cases of severe decomposition or major fire, pathological findings or DNA may be difficult, even impossible, to assess. In a large number of cases, therefore, forensic odontology has been a key to successful identification. However, with the growing number of individuals and the higher quality of dental care, the number of individuals without individualizing findings will become the norm. Finally, in children, a precise estimation of age will be possible by evaluating the dental state; however, typical findings for individualization such as inlays with different materials, crowns, or prostheses will be missing. Perhaps signs of an orthodontic treatment may be helpful.

In conclusion, DVI without forensic odontology is hardly conceivable. Odontology exclusively in scenarios with a high number of victims will miss a lot of important findings.

Radiology

The comparison of radiographs can be a very effective means for identification. However, a quick acquisition of x-rays for comparisons may be difficult. Also, the path of rays has to be comparable in standard pictures. The application of CT technology is possible, but very expensive and not feasible in all conditions. Interpretation of CT scans for identification purposes need an expert in forensic radiology and cannot be done by a clinical radiologist. X-rays of the skull (frontal sinus), fractures, prostheses, and malformations are applicable for comparisons. Dental radiography has a special relevance in identification.

Molecular genetics

DNA fingerprinting is the most important development in forensics during the last 25 years. The benefit of DNA technologies for identification is very high since international agreements made investigations and results comparable. Advantages are the high degree of safety concerning distinction between different individuals and the possibility to identify even very small portions of tissue in cases of extreme fragmentation of bodies. Familial relationships can be detected and complete families can be assigned (however, sometimes, a familial relationship is assumed before the incident, which is, in actual fact,

missing – problem of the cuckoo's child). The disadvantages are that it is a time-consuming process compared with forensic odontology and involves the impairment of the results by decomposition and degradation of DNA. Also, for DNA analysis, the comparison samples may be difficult to attend. Furthermore, the DNA analysis usually cannot be carried out in the morgue and needs special laboratories. The success of DNA techniques is not always guaranteed as experiences in the Thailand tsunami disaster demonstrated. However in DNA results, computer technology makes the data processing easier.

Forensic anthropology

The forensic anthropologist can be helpful in distinguishing human remains from nonhuman remains and in determining the gender, age, race of the victims, and the number of fatalities. Also an experienced anthropologist can easily detect certain abnormalities or individualizing traits in skeletal elements. Sometimes, additional x-ray investigations may be necessary.

Criminalistic Reconstruction

Cause and time of death investigation may belong to the data needed for a criminalistics reconstruction as well as miscellaneous findings like foreign bodies with evidence for an explosion or toxicological analysis. Carbon monoxide may give evidence that a person was alive when a fire was set. In incidents resulting from toxic agents, special analysis may be helpful in the therapy of survivors if there is a lack of information concerning the toxic substance or even a specific misinformation, as was reported in the Bhopal incident in 1984: an estimation of between 4000 and 25 000 victims.

In conclusion, victim identification after a mass disaster is an important task for police forces and all forensic, medical, and biological experts and normally a basic necessity from the ethical point of view. Cooperation between the different forensic disciplines with varying focuses concerning the type of incident will be the base of success.

Introduction

The word *forensics* is derived from the Latin word *forensis* meaning 'public.' The word 'forensic,' however, essentially implies 'of or used in courts of law.' The word 'pathology' is derived from the Greek words *pathos* meaning 'disease' and *logos* meaning 'the study of.' Forensic pathology as a speciality thus deals with both the legal and pathologic aspects of a case. Various designations are employed for specialists practicing forensic pathology in different parts of the world: forensic pathologists, medicolegal consultants, autopsy surgeons, police surgeons, medical jurists, forensic medicine experts, and so on. In this article, for the sake of uniformity, the term forensic pathologists is used for the experts practicing forensic pathology. A forensic pathologist is a pathologist who has studied the various forms of natural and nonnatural processes that lead to the death of an individual.

A key role of most forensic pathologists is the examination of a dead body, frequently known as an autopsy. 'Autopsy' is derived from the Greek words *auto* meaning 'self' and *opsy* meaning 'to look at.' Thus, autopsy means 'to look at one's self' or sometimes 'seeing with one's own eyes.' This is not very accurate when referring to a deceased person. A better word is 'necropsy,' which comes from the Greek words *necros* meaning 'death' and *opsy* meaning 'to look at.' 'Postmortem examination' is another frequently used alternative term for the examination of a dead body. All in all, autopsy/necropsy/postmortem examination may be referred to as a medicolegal examination of the dead.

Role of the Forensic Pathologist

Forensic pathology deals mostly with the pathology of intentional (homicidal and suicidal) and unintentional (accidental) trauma or injury, in cases where bodily damage may be the major finding and in deaths from natural causes in cases when the cause of death cannot be certified by a physician. In addition, deaths from occupational exposure to hazardous materials and industrial deaths may be of medicolegal significance. The primary role of the forensic pathologist is to determine the cause of death based on a detailed and complete autopsy and to confirm if the cause of death is in accordance with the manner of death as proposed by the investigating agencies enquiring into sudden, suspicious, and nonnatural deaths.

In cases involving mechanical trauma/injuries, the forensic pathologist deals mostly with the examination of the deceased or injured person to determine the nature and cause of the injuries/death. The role of the forensic pathologist is vital in cases of alleged medical negligence, sexual assault, domestic violence, and torture. In criminal investigations, in addition to the examination of the victim, the forensic pathologist may be involved in the examination of the accused/suspect, the scene of the crime/death, and the collection of evidentiary material. Thus, a forensic pathologist plays a key role in criminal cases as well as in civil cases mostly involving insurance and other claims. Besides, a forensic pathologist has to attend courts of law as an expert witness, provide valuable opinion on the cases, and thus, help in the administration of justice.

Medicolegal Systems and Investigation of Deaths

The Medical Examiner and Coroner systems exist in the United States for medicolegal investigation of sudden, suspicious, and nonnatural deaths. In Australia and England and Wales, the authority to investigate death lies with a coroner, while in Scotland, the Procurator Fiscal system is responsible for the medicolegal duties. Other countries in Europe follow procedures and systems that are different from both Coroner and Medical Examiner systems. In most of the European and Asian nations, the forensic medical expert examinations are conducted based on the decision of investigating and interrogating agencies, the prosecutor, or the court.

Aims of Medicolegal Autopsy

The autopsy involves the standardized dissection of a dead body primarily to determine the cause and manner of death. Other aims of a medicolegal autopsy are to estimate the time since death, establish the identity of the deceased, and collect essential evidences surrounding the death. A medicolegal autopsy thus answers the basic questions of 'why,' 'how,' 'when,' and 'who' with regard to sudden, suspicious, and nonnatural deaths.

Cause of Death

If a person dies under suspicious or nonnatural circumstances, the investigating authority orders an autopsy to determine the cause of death. The cause of death is the injury or disease that produces a physiological derangement in the body, resulting in the death of an individual.

The cause of death is divided into the primary and secondary causes of death. The primary cause of death includes the immediate and antecedent causes responsible for the fatal outcome, while the secondary cause of death includes the conditions that are not related to the primary cause of death but contribute substantially to the death of an individual. Format frequently followed for documenting the cause of death is depicted in Table 1.

For example, in a case of a fatal fall from the stairs, an elderly male suffering from senile dementia sustained head injuries. The autopsy revealed extradural hematoma in the right temporoparietal region. The cause of death can be mentioned as:

- Part I
 - (a) Extradural hematoma: due to (or as a consequence of)
 - (b) Blunt force trauma to the head: due to (or as a consequence of)
 - (c) Fall from stairs
- Part II: Senile dementia

Manner of Death

The manner of death explains the circumstances associated with the death and the way in which the cause of death came about. Broadly, the manner of death can be natural or

Table 1 Format frequently followed for documenting the cause of death

<i>Cause of death</i>	<i>Approximate interval between onset and death</i>
Part I. Diseases, injuries, or complications that caused the death. Do not enter the mode of dying, such as cardiac or respiratory arrest, shock or heart failure	
Immediate cause (a)	Due to (or as a consequence of)
Antecedent cause (b)	Due to (or as a consequence of)
(c)	Due to (or as a consequence of)
Morbidity conditions, if any, giving rise to the above cause, stating underlying conditions last	
Part II. Other significant conditions contributing to death but not resulting in the underlying cause given in Part I	

nonnatural. Nonnatural manner of death can be further classified as homicidal, suicidal, or accidental depending on the intent of the act leading to the death of an individual. Commenting on the manner of death may be a complex task. In cases where it is difficult to reach a definitive conclusion as to the manner of death, it is of utmost importance that a systematic death scene investigation, a meticulous postmortem examination, and an intelligent interpretation of the findings are carried out before a final comment on the manner of death is made.

Medicolegal Autopsy

The autopsy is a standardized procedure that comprises of a detailed external and internal examination and collection of evidentiary material. It should be kept in mind that the identity of the body is confirmed before starting the autopsy. The identity of the deceased is usually established by the near relatives of the deceased and the investigating officers. In cases of unidentified bodies, photographs are taken and identification marks are noted on the body. Examination of any congenital or acquired abnormality may help in establishing the identity of the deceased. In cases where the visual identification is difficult as in cases of dismembered, mutilated, and charred remains, dental examination and DNA profiling are often used to confirm the identity of the unknown person.

External Examination

The external examination of a body besides a detailed examination of the entire body also includes a description of the clothing of the deceased and photographs of the body. Any trauma observed on the body is noted in detail with measurements, and the same is correlated with the damage to the clothing, if any. Clothing is then removed from the dead body with utmost care, and trace evidence on the clothing or the body is preserved for further analysis at the forensic science laboratory.

After removal of clothes, the age, sex, general physique (height and weight), and state of nutrition are noted. Examination of the eyeballs and external body orifices is essential. Postmortem changes in the body are appreciated as they primarily give an insight into the time since death. Postmortem changes frequently observed on external examination that help in estimating the time of death include algor mortis, livor mortis, rigor mortis, degree of decomposition, and insect activity. In cases of mechanical violence and traumatic deaths, a detailed description of the external injuries is vital. All recent and old injuries should be photographed and described in detail with regard to their size and location on the body.

Internal Examination

The internal examination follows a detailed external examination. Internal examination starts with the dissection of the dead body and naked-eye inspection of underlying tissues and organs. The prime object of internal examination is to examine the contents of the head, neck, thorax, and abdomen for injuries/pathology.

The forensic pathologist examines the thoracoabdominal cavity usually following one of the following techniques:

Virchow method: In the Virchow method, each organ is removed one by one and examined in detail.

Rokitansky method: In the Rokitansky method, in situ dissection and removal of organs are carried out.

Ghon method: The Ghon method is characterized by en bloc removal of organs.

Letulle method: The Letulle method is characterized by en masse removal of cervical, thoracic, abdominal, and pelvic organs and their subsequent dissection into organ blocks.

Whenever required, the internal examination is followed by microscopic, biochemical, immunologic, and toxicological investigations.

Importance of Additional Investigations

Histology, postmortem biochemistry, and evaluation of postmortem parameters of metabolic dysfunctions, immunohistochemistry, postmortem toxicology, x-rays, and modern methods of imaging such as computed tomography (CT), postmortem CT angiography, and magnetic resonance imaging (MRI) are important additional investigations frequently used in modern autopsy work.

In cases of sudden unexpected deaths, the gross autopsy findings may be inconclusive, and histopathological evaluation may play a crucial role in defining the cause of death. Postmortem biochemical examinations of vitreous humor, blood, urine, and cerebrospinal fluid are other important and useful investigations in forensic autopsies that help in determining the cause of death. Biochemical markers of inflammation and infection, hormonal disturbances, alcohol intake and abuse, cardiac function status, and ischemia are reported. Postmortem analysis of glycated hemoglobin, C-reactive protein, interleukin, cholesterol, triglycerides, total bilirubin, total proteins, albumin, and troponin 1 in blood and sodium, potassium, chloride, and glucose in vitreous helps in determining the cause of death. Besides, determining the cause of death,

postmortem chemistry helps in understanding the pathophysiological mechanisms involved in the death process.

Vitality and wound age estimation are the central issue in investigation of injuries and traumatic deaths. Morphological methods such as routine histology and enzyme histochemical methods are routinely employed for vitality and wound age estimation. Immunohistochemistry is the modern investigation of choice in this regard. Besides, biochemical methods are employed in evaluation of vitality.

Radiological investigations including x-rays, CT, MRI, and angiography are useful in determination of identity and evaluation of injury and death. Role of radiological techniques in analysis of gunshot wounds and osseous injuries is well known. With radiological advancement, use of modern imaging techniques is being considered an alternative to traditional autopsies in determining the cause of death. Radiological investigations can help in analysis of complex trauma pattern and fractures, and finding the location of foreign bodies and metal fragments. These are advantageous in detection of pneumothorax. Postmortem angiography can be used in evaluation of cardiovascular and hemodynamic conditions.

Evidentiary Material Collected at Autopsy

Blood samples are usually collected for chemical, toxicologic, and serologic investigations. Blood is preferably taken from peripheral veins from the groin or the neck.

In cases of suspected poisoning, the stomach and its contents, a piece of liver with gall bladder, and both kidneys are subjected to chemical and toxicologic analysis.

In addition, specific viscera and body fluids should be preserved depending on the nature of poison allegedly consumed.

In cases of alleged sexual assault, swabs are collected from genitalia for examination of body fluids along with pubic hair combs to identify any foreign materials.

In cases of gunshot wounds, the clothing and the recovered bullets are preserved and sent for forensic analysis.

In cases of unidentified bodies, fingerprints are taken and matched with the reference databases.

In decomposed, mutilated, and dismembered remains, the teeth are subjected to a forensic dental examination and DNA analysis.

Attendance of a Forensic Pathologist at the Scene of Crime/Death

The death scene should ideally be examined by a team comprising of investigating police officers, forensic scientists, and forensic pathologists. The help of forensic anthropologists may be sought in the examination of skeletal remains, that of entomologists in the examination of insects, and that of odontologists for dental examination. The inclusion of forensic pathologist in the death scene investigation team is important in examining the deceased at the scene and in reconstruction of events. Wound pattern analysis is an essential component in reconstruction of events. Wound pattern analysis and its correlation with the observations made at the scene of death can be vital in reconstruction of events. In cases of suspicious

deaths, the forensic pathologists visiting the scene of death can provide vital information on the manner and circumstances of death. Moreover, the scene of death is possibly the best place to make an estimate of the time since death. Forensic pathologist at the scene of death can ensure that the vital evidence is not lost and that the same is collected appropriately. The attendance of a forensic pathologist at the scene of crime/death varies from case to case and in different set ups. Scene examination that is often not considered an integral component of autopsy can thus have serious implications.

Conclusion

Forensic pathologists are required to work in close association with other specialities of the forensic sciences. Forensic pathologists play a significant role in cases of suspicious and non-suspicious deaths. In cases of sudden death, they establish the exact cause of death, while in criminal cases, their opinion is vital to the delivery of justice. The information obtained from investigating accidental deaths and suicides can be vital to designing preventive strategies. In view of the importance of forensic pathology as a speciality, its development is essential in modern society. Association of forensic medicine and pathol-

ogy with issues of public health, occupational health, and community health needs to be addressed and emphasized on.

External Postmortem Examination

B Madea and G Kernbach-Wighton, University of Bonn, Bonn, Germany

© 2013 Elsevier Ltd. All rights reserved.

Introduction

The external postmortem examination is of significance with respect to the following issues:

- death certification
- as part of the autopsy
- for identification purposes (e.g., identification of disaster victims)

The external examination of each deceased person by a physician has the greatest practical relevance because it is required for death certification.

External Examination Before Death Certification

For the external postmortem examination, the physician has to fulfill a wide range of tasks concerning different legal and social aspects (Table 1). The terminology of death certification can be found in Table 2.

The first and most important purpose of the external postmortem examination is the determination of death, not only in the interest of the decedent but also as a social requirement.

Safe determination of the cause of death and underlying diseases is also essential.

Mortality statistics and resource sharing in the health-care system are both based on data on underlying diseases and causes of death. An exact definition of the manner of death is essential to guarantee legal certainty but may also have consequences in other legal areas (civil law, insurance law, or compensation law).

The legal bases for external postmortem examinations vary from country to country and even between different counties within one country. An external postmortem examination has to be carried out once a dead body is found.

- A human corpse is:
 - The body of a dead person as long as tissue continuity has not been destroyed by putrefaction.
 - The body of a dead neonate (irrespective of the body weight) if it has completely left the womb and if after leaving the womb it showed one of the three signs of life (heart beat, umbilical pulsation, and breathing).
 - A stillbirth (stillborn baby weighing ≥ 500 g).
 - The head or torso separated from a body that cannot be reassembled.
- The following are not corpses:
 - Skeletons either partial or complete.
 - Miscarriages (stillborn fetuses with a birth weight < 500 g; no requirement to report the death).

The body should be examined without delay once notice of the death has been received. In many countries, any physician may certify a death, but in some counties, a physician who is

related to the deceased may not be allowed to certify a death. Every private practice physician (in the area covered by his or her practice) and hospital physicians has the obligation to certify a death. A careful examination of the naked body is mandatory. Careless examination of a body may constitute a regulatory offense. If living people are injured as a consequence of careless medical examination of a dead body, charges may be made against the physician in charge (if, for instance, carbon monoxide poisoning is overlooked and other persons also suffer asphyxiation by carbon monoxide). Emergency doctors may complete a preliminary death certification, but the regular external examination has to be carried out by another doctor (this varies from country to country).

Cases in which the manner of death is unnatural or unexplained, or the identity of the body is unknown, have to be reported to the police. All cases that fall under the Infection Protection Act have to be reported to the local health office. All doctors who have previously treated the deceased have to provide necessary information if asked to do so.

Determination of Death/Death and Dying

Definitively establishing that death has occurred is straightforward. Cessation of vital functions can be determined with certainty by the following criteria:

- Presence of definite signs of death (livor, rigor, advanced postmortem changes).
- Failure of attempted resuscitation for approximately 30 min, confirmed by approximately 30 min of a flatline electrocardiogram (ECG) despite carrying out appropriate measures and after ruling out general hypothermia or intoxication by central depressant drugs.
- Brain death (can be determined under clinical conditions only during assisted ventilation).
- Physical trauma that is incompatible with life.
- Determination of death is uncomplicated if there are obvious postmortem changes (e.g., rigor mortis, livor mortis, putrefaction, and injuries that are incompatible with life).

Apparent Death

Determination of death might be difficult within the phase of *vita minima* and *vita reducta* with increasing devitalization before certain death signs appear because of heart and circulatory arrest. Within *vita minima* and *vita reducta* with dysregulation of functional systems and their coordination and increasing devitalization, life expressions (respiration and circulation) may be abandoned and might not be seen when examined superficially. Causes and conditions leading to *vita minima* and *vita reducta* were summarized by Prokop, a medical examiner from Berlin, who called it the 'AEIOU rule' (Table 3).

Great care is required if there is suspicion of conditions according to the AEIOU rule, meaning intoxication with hypnotics, carbon monoxide, and alcohol; hypothermia; electrical accidents; apoplexy; brain pressure; metabolic coma; epileptic seizures; hypoxic brain damage; missing life expressions; and missing certain signs of death at the same time. In these cases, the following is essential.

Do not fill out any death certifications if there are no certain signs of death.

In case of doubt, the physician has to wait for help (emergency doctor) or admission to a hospital has to be arranged. In any case, the behavior of the physician depends on information about the anamnesis and patient's prognosis.

The so-called uncertain signs of death such as fixed pupils, wide pupils, areflexia, loss of cardiac activity, loss of respiration, and dropping core temperature are meaningless if

an examination has been done improperly, especially if the reversibility/irreversibility of the condition has not been questioned (Table 4). For example, absence of a peripheral pulse within the centralization of the circulation, as in cases of hypothermia, does not say anything about a lack of cardiac activity. Minimum breathing excursions from abdominal respiration do not 'catch one's eye' in fully clothed persons. A body surface that feels cold when the ambient temperature is low or wet clothing is worn does not give any information about the core temperature. When pupil width is estimated, possible intoxication always has to be kept in mind (the so-called ABC toxins: alcohol, amphetamine, belladonna, and cannabis).

From the medical and legal points of view, failure of heart resuscitation is a reliable criterion to stop a correct but unsuccessful reanimation. Normally, one will stop cardiopulmonary

Table 1 Functions and importance of the external postmortem examination

1. Determination of death	Social and individual interest in correct determination of death, ending of the normative protection of life, civil registers
2. Determination of the cause of death	Medical aspects, mortality statistics, epidemiology, resource sharing within the health-care system, development of public health programs, allocation of health-care resources
3. Manner of death	Legal security, detection of homicides, classification of conditions of death on requests by civil law, insurance law, or compensation law
4. Determination of time of death	Civil registers, inheritance law
5. Transmitted diseases according to the Infection Protection Act	Hygienic aspects as social interest
6. Obligations to report	– If the manner of death is unnatural/undetermined – If the identity of the deceased is not known – According to the Infection Protection Act

Table 2 Terminology of death certification

Term	Definition
Cause of death statement	Included in part I and part II of the certification of death
Underlying cause of death	The reason/alteration standing at the beginning of the course of events resulting in death
Immediate cause of death	The last circumstances caused by the underlying conditions directly linked to the occurrence of death
Antecedent ('intervening' or 'intermediate') cause of death	An alteration also caused by the underlying conditions, but not defined as the immediate cause of death
Mechanisms of death	Physiological or biochemical alterations resulting in death via their lethal effects, but not equivalent to the underlying cause of death
Manner of death	Death classification based on five definitions: natural, homicidal, suicidal, accidental, or undetermined taking into account the actual circumstances

Table 3 Complexes of causes for *vita minima/vita reducta*

A – alcohol, anemia, anoxemia
E – electricity, stroke of lightning
I – injury (head injury)
O – opium, anesthetics, neuropharmacological drugs
U – uremia (and other metabolic coma), hypothermia

Source: According to Prokop.

Table 4 So-called uncertain signs of death

*Apparent death – *vita minima* – *vita reducta**

- Fixed pupils, dilated pupils
 - Areflexia
 - Missing cardiac activity
 - Dropping core temperature
- Are no 'uncertain signs of death' because of
- Absence of peripheral pulse $\neq$ absence of heart activity
 - Minimum breathing excursions within abdominal respiration do not 'catch one's eye' in fully clothed persons
 - Body surface may feel cold when the ambient temperature is low and wet clothing is worn
 - Was it tested, maybe on hands? – $\neq$ core temperature (warmth regulation in coldness – minimum blood)
 - Flow
 - Pupils' width? Reaction to light stimulus? ABC toxins
 - Proprioceptive and polysynaptic reflexes, other reflexes than corneal reflex?

resuscitation if there is no success after 30–40 min or if heart reactivation seems unlikely. This includes the following criteria:

- Absence of spontaneous electrical activity (zero voltage line in the ECG).
- Signs of electromechanical decoupling (deformed QRS complexes in the ECG but absence of palpable pulse on large vessels).
- Continuous ventricular fibrillation with frequency deceleration and a progressive decrease in amplitudes.
- These signs show definite and irreversible cardiac death if the patient is normothermic and there are no other specific conditions.
- If patients are hypothermic, if they are near-drowning victims, or in cases of intoxication, resuscitation has to be performed longer than the time specified earlier until detoxification occurs or the body warms up. Only then does the decision to stop reanimation make sense.

Centrally acting medication and general hypothermia have to be excluded. Emergency doctors have formulated the principle: 'No one is dead until he is warm and dead.' Determination of death may follow if resuscitation is unsuccessful and the core temperature is at least 32°C or below.

Brain Death

Brain death is defined as the irreversible loss of general functions of the brain, cerebellum, and brain stem, whereas heart and circulatory functions may be maintained by controlled ventilation. Brain death is the death of a human being. The criteria for brain death are:

1. *Requirements*
 - acute severe primary or secondary brain damage
 - exclusion of intoxication, neuromuscular blockade, hypothermia, circulatory shock, and metabolic and endocrine coma
2. *Clinical symptoms*
 - unconsciousness/coma
 - fixed pupils of both medium or strongly dilated pupils (no application of mydriatic drugs)
 - absence of oculocephalic reflex
 - absence of corneal reflex
 - absence of pain response in the trigeminus area
 - absence of pharyngeal reflex
 - loss of spontaneous respiration
3. *Supplementary examination*
 - zero voltage line in the electroencephalogram (EEG)
 - termination of evoked potentials
 - cerebral circulation arrest

Time Since Death

The procedure for ascertaining the time of death depends on the nature of the case (Table 5). Medical examiners use a wide range of methods, which are outlined in the article about postmortem changes and estimation of the time since death.

Table 5 Ascertaining the time of death

– <i>Death under medical supervision</i>
● Document the time of observed cardiovascular arrest
– <i>Dead body found</i>
● Establish upper and lower time limits by stating the following:
● Last signs of life on ...
● Found dead on ... or
● Estimate how long the body has been dead on the basis of how far the signs of death have advanced
– <i>Cases in which death occurred after brief agony and was observed by witnesses</i>
● Time of death as reported by relatives, witnesses, etc.
– <i>Care must be taken when near relatives die more or less simultaneously (e.g., childless couple)</i>
● Documentation must be very detailed and correct because there may be issues related to inheritance

Determining the Cause of Death

In the confidential part of the death certificate, under the heading 'Cause of death,' the course of the disease is documented within a causal chain (Figure 1).

The immediate cause of death is given in Part Ia and the preceding causes – diseases that resulted in the immediate cause of death – in Parts Ib and Ic, with the underlying disease(s) coming last. Finally, other important diseases that contributed to death but are not linked to the underlying diseases are given in Part II. The most important epidemiologic information is derived from the underlying cause of death, which is used for mortality statistics.

The major significance of the cause of death is a statistical one: how many people die from a certain disease? This is opposed to the final cause of death, which gives information about what people are suffering from and the particular disease that caused their death.

According to Federal Statistical Office recommendations, if nothing precise is known, the entry 'cause of death unknown or unascertained' is preferable to vague speculation. Under no circumstances should constituent elements of every death process, such as 'cardiac arrest,' 'respiratory arrest,' or 'electromechanical decoupling,' be included in any part of the cause of death cascade, from underlying disease to the immediate cause of death.

Then, in the right column, the duration (time interval) of the disease has to be recorded, taking as the starting point the estimated onset of the disease and not the time of diagnosis. The entries on time intervals also work as a plausibility check on the cause of death cascade. For adequate certification of the cause of death, knowledge of the medical history of the patient and the circumstances leading to her or his death are essential. A careful analysis of the relationship between the medical history and medical treatment may already provide important information for the cause of death certification. If the deceased is not personally known to the certifying physician, appropriate information is required from the treating physician.

A formal and correctly arranged cascade for mortality statistics leading from the direct cause of death to the underlying disease would be, for example:

Cause of death		Approximate interval between onset and death
I Immediate cause* Enter diseases, injuries, or complications that caused death. Sequentially list conditions leading to immediate cause; enter underlying cause last.		
a)	due to (or as a consequence of)	
b)	due to (or as a consequence of)	
c)	due to (or as a consequence of)	
d)	underlying condition	
II Other significant conditions contributing to death but not to the underlying cause 		
<i>* This does not mean the manner of dying, e.g., cardiac arrest, respiratory arrest, etc. It means the disease, injury, or complication which caused death.</i>		

Figure 1 International form for cause of death medical certificate.

- (Ia) esophageal variceal bleeding as a consequence of
- (Ib) backflow within the portal vein
- (Ic) liver cirrhosis (underlying disease)
- (II) diabetes mellitus or
- (Ia) retention pneumonia
- (Ib) obturating bronchial carcinoma

If the cause of death given in Ia is not the consequence of further complications or underlying diseases known from the patient's history, no further entries are needed, for example:

- (Ia): Cranial gunshot wound

Final indirect causes of death can be divided into the organ-related ones and those that are not organ-related.

Within the prestructured entries on underlying disease and cause of death on the death certificate, according to World Health Organization guidelines, physicians should mentally review the entire history of their patient's illness. In particular, they should ask themselves whether such a final morbidity was present that would be expected to lead to the patient's death at the time given by the circumstances described. 'Hard' and 'soft' causes of death should be distinguished: hard causes of death are present when the underlying disease of death and immediate cause of death are closely related, appear in a close sequence in time, and there is a close causal relationship between them, for example, in a case of clinically diagnosed myocardial infarction resulting in cardiac rupture and hence pericardiac tamponade. Here, the underlying disease and immediate cause of death are present within one organ system (linear type of death).

Soft diagnoses are, for example, characterized by a patient who suffers from more than one underlying disease, none of which suggests itself a priori as the cause of death, and the cause of death remains multifactorial.

In addition, one may be guided by 'death types' that have been described as a 'thanatological bridge' between the underlying disease and the immediate cause of death (**Figure 2**):

- *Linear type of death*: Underlying disease and immediate cause are within one organ system
- *Diverging type of death*: Organ-specific underlying cause but non-organ-specific immediate cause
- *Converging type of death*: Underlying diseases in various organ systems lead to death via a final pathogenetic phase common to all of them
- *Complex type of death*: Underlying diseases in various organ systems with more than one non-organ-specific immediate cause of death

If the cause of death remains unclear in a case of unexpected death of a healthy person, this should be noted on the death certificate. Federal Statistical Office recommendations on entering the cause of death and important terms are given in **Table 6**. When only insufficient information is available to describe the immediate cause of death, for example, because the patient did not seek medical attendance, descriptive statements should be used, such as prostate carcinoma with lung and bone metastases or found dead with a history of severe coronary atherosclerosis and recent myocardial infarction.

Finally, particular problems arise with deaths due to old age or in connection with medical procedures. 'Senility' and 'old age' are not causes of death. Retrospective examinations of deaths of those over 85 years and over 100 years old have shown that in each case, morphologically ascertainable underlying diseases and immediate causes of death were present. If appropriate, the diagnosed diseases that contributed to the occurrence of death can be descriptively listed as a multifactorial converging type of death in order to avoid 'makeshift' diagnoses.

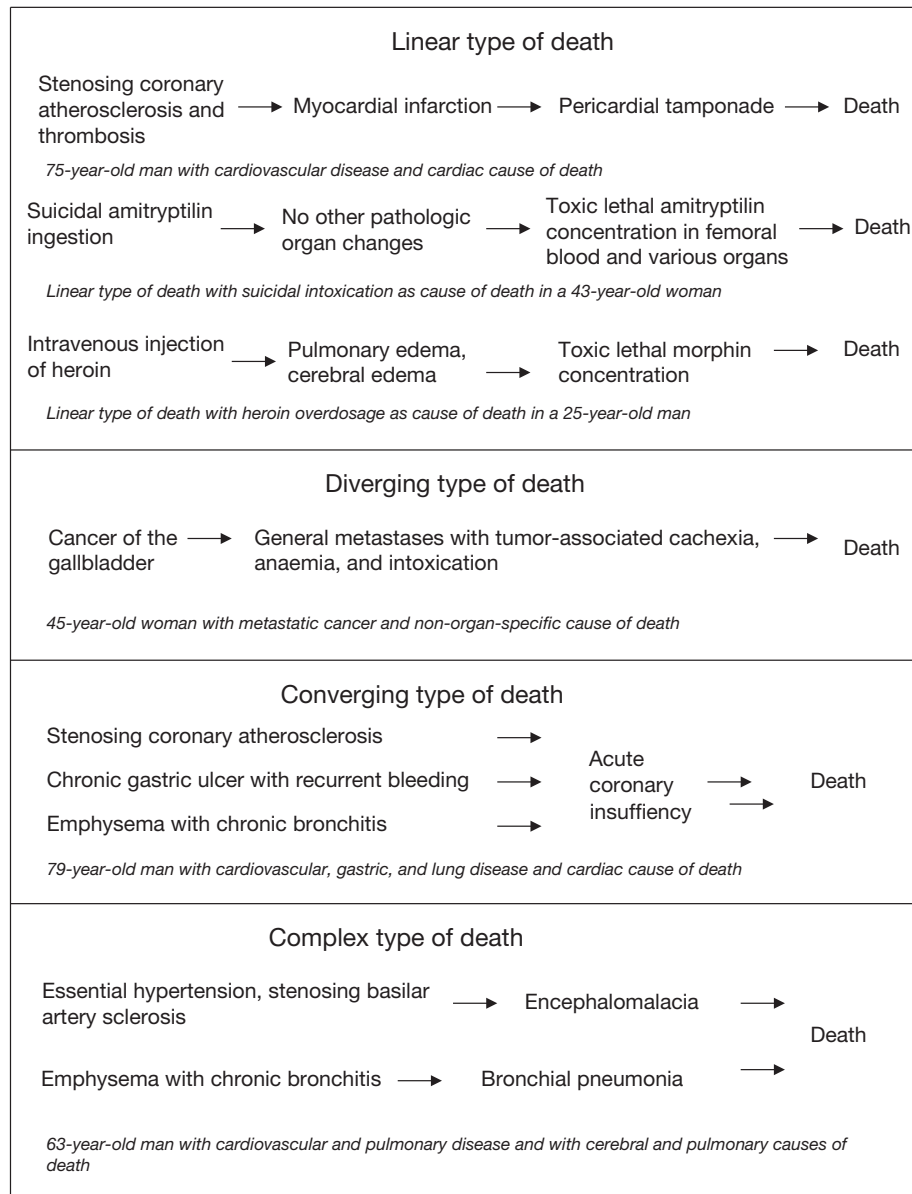

Figure 2 Types of death (according to Leis and Thieke and Nizze): case examples from Thieke and Nizze.

Regarding deaths attributable to medical procedures, the first notable point is a considerable discrepancy between the deaths recorded in the federal statistics as due to complications of medical and surgical treatment and the data derived from epidemiological research on death cases due to maltreatment.

Epidemiological research for Germany revealed that 17 500 deaths per year are suspected to be the results of medical malpractice – these figures are consistent with international data – whereas the Federal Statistical Office mentions 399 deaths only as complications of medical and surgical treatment in 2007. It clearly appears that a considerable number of unreported cases exist, raising the question of whether under relevant circumstances the attending physician should issue the death certificate or whether, irrespective of the existence or otherwise of suspicion, such cases should always be subject to an official investigation.

Consistency Between Cause of Death Diagnosis on the Death Certificate and Following Autopsy

Numerous studies have been published on the validity of the clinically determined cause of death as entered on the death certificate in comparison to pathoanatomical findings. The Görlitz study (1986–87), with a nearly 100% autopsy rate (1060 deaths out of which a postmortem was carried out in 1023), showed incongruity between certificate and autopsy findings in a total of 45% of male deaths and 48.8% of female deaths. Among hospital deaths, there were incongruities of the underlying disease in 42.9% of men and 44% of women; among deaths in care homes, the corresponding figures were 63.2% of men and 57.8% of women; for deaths occurring elsewhere (at home, in public, etc.), the results were 41.3% of men and 50.7% of women. Among iatrogenic deaths, the rate

Table 6 Causes of death: examples and important aspects

Pneumonia	– Primary, hypostatic, aspiration, other underlying cause – Pathogen
Infection	– If seen as a consequence of immobility or debility: the cause of the immobility or debility – Primary or secondary pathogen – If primary: bacterial or viral – If secondary: more information about the primary infection required
Urinary infection	– Localization in the urinary tract, pathogen, other underlying cause – If a consequence of immobility or debility, the cause of the immobility or debility
Renal failure	– Acute, chronic, or terminal; underlying cause (e.g., hypertension, atherosclerosis, cardiovascular disease) – If a consequence of immobility or debility, the cause of immobility or debility
Hepatitis	– Acute or chronic, alcohol-related – If viral: type (A, B, C, D, or E)
Infarction	– Atherosclerotic, due to thrombosis or embolism
Thrombosis	– Arterial or venous – include vascular designation – Intracranial sinus – purulent, nonpurulent, venous (state which vein) – If postoperative or in an immobile patient: disease that was the reason for surgery or immobilization
Pulmonary embolism	– If younger than 75 years: cause – If postoperative: disease that was the reason for surgery or immobilization
Leukemia	– Acute/subacute/chronic – Lymphatic/myelogenous/monocytic
Alcohol/medical drugs/narcotics	– Long-term abuse or drinking – Dependency
Complication of surgery	– Disease that was the reason for surgery
Dementia	– Cause (e.g., senility, Alzheimer's disease, multiple infarction)
Accidental death	– Details of circumstances (e.g., bicyclist hit by a car) – Accident, suicidal, violent assault, or circumstances unknown – Accident site (e.g., in the street, at home, etc.), activity at the time of death (playing golf, going to the movies, working, etc.)
Tumor	– Benign, malignant, location, metastases

Source: According to Federal Statistical Office recommendations.

of incongruities between underlying diseases as determined clinically and found at autopsy was as high as 72%, and inconsistencies for the immediate causes of death were 45.8%.

Numerous studies have differentiated and operationalized the discrepancies between clinically determined causes of death and those determined at autopsy (major mistake, class 1; major mistake, class 2; minor mistake). According to various statistics, class 1 major mistakes, which have consequences for the treatment and survival of the patient, occur in 11–25% of all deaths, while class 2 major mistakes, which have no consequences for treatment and survival, are found in 17–40% of deaths.

According to a meta-analysis by Shojania et al., class 1 major mistakes have decreased in the past 40 years but do still occur in about 8–10% of deaths.

Manner of Death

According to cause-of-death statistics, around 4% of deaths in Germany result from unnatural causes (Figure 3). Around 10 000 cases per year are due to suicide, 6000 are caused by accidents at home, just under 6000 result from transport accidents, and 526 deaths result from physical assaults.

Retrospective analyses of death certificates for which the manner and cause of death have been checked at autopsy suggest that unnatural deaths are around 33–50% more

frequent than reflected in the federal statistics and that it could be assumed that there are around 81 000 unnatural deaths every year. From the judicial point of view, a particular concern is the number of homicides that remain undiscovered by means of medical death certification. A multicenter study suggests that every year around 1200 homicides remain unidentified on death certificates in Germany. This large number of unrecorded cases was repeatedly confirmed by incidental findings of homicide or even serial murders (including those in care homes and hospitals). Six percent of hospital physicians regularly attest exclusively natural death; 30% tick the box for natural death even in cases of violence, poisoning, suicide, or following medical intervention. In assessing the manner of death, the certifying physician decides whether a death will come to the attention of the investigating authorities at all. Assessing the manner of death is thus a task requiring extreme responsibility not only from the judicial point of view (detection of homicides) but also in terms of the interests of the bereaved (e.g., compensation claims after a fatal accident). 'Natural' is death from an internal cause (disease), when the deceased person has suffered from a disease that can be identified precisely and from which death was anticipated; the death occurred entirely independently of any external factors of legal significance. The prerequisite for attesting a natural death is thus the existence of an underlying disease of death known from the patient's medical history with a poor prognosis for survival.

'Unnatural,' by contrast, is death attributable to an event caused, triggered, or influenced from outside, irrespective of

Figure 3 Causes of death. Proportion of unnatural causes of death among deaths in Germany, 2007. Source: Federal Statistical Office.

whether due to the fault of the patient himself or herself or of a third party. Unnatural deaths, therefore, are those due to:

- Physical assault
- Accident (irrespective of whose fault)
- Homicide
- Poisoning
- Suicide
- Treatment errors/medical malpractice
- Fatal consequences of any of the first six points

The interval between an external event at the beginning of the causal chain that leads to death and the occurrence of that death can thus be indefinitely long (it may be years). If the cause of death cannot be ascertained when the death certificate is issued, the manner of death will therefore also remain unclear.

The attestation of natural death always assumes that a clear cause of death can be given. In this connection, it is worrying that about 50–70% of physicians certify a ‘natural’ death for deaths following femoral neck fractures, 20% for deaths during injections, and 30–40% for intraoperative deaths.

If on the one hand unnatural deaths are considerably underrepresented in official statistics, and on the other hand both physicians in private practice and those working in emergency departments report attempts by the police to influence them to certify a death as natural although no cause of death is apparent, the death ought to be certified at least as unexplained. In an anonymous survey of randomly selected physicians from the area of the Westphalia–Lippe Medical Association, 41% of physicians in private practice and 47% of emergency room physicians reported such attempts to influence death certification. The background of these attempts is that investigating authorities have a teleologically narrowed understanding of the term ‘unnatural death’ as meaning ‘death in which there is a possibility of third-party guilt.’ If a natural death is certified, no further investigations are necessary. Indicators that a death may be unnatural may arise from the case history and findings: for example, sudden death without a known previous illness,

‘prima facie’ accidents and suicides, farewell letters, etc. Findings that tend to indicate unnatural death are conjunctival hemorrhages, unusual color or livor mortis, remains of tablets in the oral area, and signs of injury.

Unsuitable criteria for indications of natural death are age, especially when no preexisting life-threatening diseases are known, and the absence of visible trauma.

Regarding deaths in hospital, especially when the patient was under medical treatment for a long enough period, the error rate should also be relatively low; problem areas here are failure to identify causal connections to trauma at the beginning of the fatal causal chain and deaths related to medical procedures. In the inpatient setting, there are occasional reports of initially unrecognized series of killings by physicians or nursing personnel.

The danger of errors and scope for deception are without doubt greatest when death is certified by private practice physicians at home; typical mistakes and sources of error, in order of frequency, are:

- Inexperience
- General carelessness
- Careless examination of the body
- Consideration of the emotional state of relatives

Furthermore, however, there are sometimes also unfavorable external conditions, such as poor lighting, and simply not being adept at the job, and there are no flexible solutions such as calling in an appropriately qualified certifying physician. Physicians in private practice especially can find themselves being confronted with a collision of interests, such as also being the physician for the relatives of the deceased. Attesting an unexplained death puts them at risk of triggering investigations that could mean losing the relatives as patients. Compared to a physician working in private practice, the hospital physician finds himself in a more protected position (death in the medically dominated environment of a hospital rather than in the private area).

Problem Areas

Problems that may repeatedly arise within the hospital context are:

- Deaths in connection with medical interventions and
- Deaths following injury from a fall or other violent events in which the causal connection with violence from another person or other external event is not identified and therefore death is wrongly certified as natural

For deaths occurring unexpectedly that are linked to medical interventions, the manner of death should always be certified as ‘unexplained’ so that an official autopsy can be carried out to investigate the underlying and immediate causes of death objectively. This is the only basis from which an opinion can be expressed on any question of maltreatment. Certifying the manner of death as unexplained or unnatural does not signify an admission of maltreatment.

For physicians in private practice, the main problems may arise when bodies are found at home, patients die unexpectedly, and death occurs because of old age.

If the cause of death cannot be established from external examination of the body or from interviewing any doctors previously involved in treatment, this should be recorded and the manner of death certified as unexplained. With the elderly, there is always the question as to whether the case history and severity of the diagnosed disease explain the occurrence of death at this particular moment.

Whenever the cause of death cannot be established by external examination, an autopsy should be carried out, as is still usual in many countries in Europe. In Germany, the present autopsy rate is less than 5% of all deaths; the rate of hospital autopsies in particular has been dropping sharply in recent years, while judicial autopsies have remained relatively stable at 2% of deaths (compared to autopsy rates of 20–30% in England, Scotland and Wales, Sweden, and Finland).

These autopsies, which are required for valid cause of death statistics and for the national mortality registers, would however have to be remunerated adequately, which unfortunately they are not at present.

Autopsy

P Saukko, University of Turku, Turku, Finland

S Pollak, Universitätsklinikum Freiburg, Freiburg, Germany

© 2013 Elsevier Ltd. All rights reserved.

Semantically, the most accurate description of the dissection of a dead body is 'necropsy,' though the word 'autopsy' (from the ancient Greek 'autopsia,' 'to see for oneself,' from αὐτός (autos, 'oneself') and ὥψις (opsis, 'eye')) is so extensively used that there is rarely ambiguity about its meaning. Another alternative, albeit less precise is 'postmortem examination.' It is a detailed systematic external and internal examination of a corpse usually carried out as a hospital autopsy by a pathologist or as a medicolegal one, by one or more medicolegal experts to ascertain the immediate, underlying, and possible contributing causes of death, and in the latter type of autopsy depending on the jurisdiction, also the manner of death. However, in some parts of the world where autopsies are seldom performed, this may be limited to external examination of the body without dissection.

'Verbal autopsy' is used as a public health tool to find out the probable causes of death in populations, mainly in Africa and Asia, lacking vital registration and medical certification. Verbal autopsy is an interview carried out with family members and/or caregivers of the deceased using a structured questionnaire to find out signs and symptoms and other relevant information that can later be used to assign a probable underlying cause of death.

Short Historical Overview

Anatomical Dissection

The prerequisite for the whole idea of an autopsy or necropsy was the knowledge of human anatomy, and the history of autopsy shows three, partly overlapping, paths of development: anatomical dissection, medicolegal autopsy, and clinical or hospital autopsy. The first of them lasted almost 2000 years from the first known school of anatomy in Alexandria around 320 BC, where human dissections were carried out, till the publication of the great textbook of anatomy *De humani corporis fabrica* in 1543 by Andreas Vesalius (1514–1564), the 'Father of Anatomy,' marking the overthrow of traditional Galenic anatomy.

The possibility to dissect human bodies varied greatly at times. There are reports on occasional dissections that took place in the twelfth and thirteenth centuries. Probably one of the earliest known is the one ordered by the Norwegian King Sigurd Jorsalfar in 1111. On his return from Jerusalem with his followers, they stopped in Byzantium (present Istanbul), where many of them died, and Jorsalfar ordered a dissection to find out whether the cause of death had been liver damage by too strong wine. In 1391, the University of Lérida in Spain was given permission by King John I of Aragon to dissect the body of a criminal once every 3 years.

In Vienna, the first anatomical dissection took place in 1404 and in Prague, somewhat later in 1460.

A rare and good consideration to the practice of post-mortem examination in the fifteenth century is given by a

collection of autopsy records, *De Abditis Nonnullis Ac Mirandis Morborum Et Sanationum Causis* – 'The Hidden Causes of Disease,' published in 1507 after the death of a Florentine physician Antonio Benivieni (1443–1502) by his brother, Geronimo. He had requested another Florentine physician, Giovanni Rosato, to choose and edit the cases for collection. Some medical historians have credited Benivieni as one of the founders of the science of pathology and he was the first physician to our knowledge to ask permission of the relatives of his patients to perform necropsies in obscure cases.

Felix Platter I., the famous anatomist in Basel, was said to have performed more than 300 autopsies since 1559 (Figure 1).

Medicolegal Autopsy

The historical development that eventually led to the present-day 'cause-of-death' investigation system and autopsy was preceded by the external examination of a dead body, the practice of which began in ancient China more than 2000 years ago. Systematic external investigation of dead bodies, particularly in violent or sudden unexpected or unwitnessed deaths, was introduced during a period called 'the Warring States' (475–221 BC). The earliest known written instructions to government officials, who had the responsibility to carry out these examinations, originate from the Qin dynasty (221–207 BC). During the Song dynasty (960–1279 AD), these officials were obliged to investigate violent or suspicious deaths within 4 h under pain of punishment.

In other parts of the world, medicolegal investigation of deaths was introduced much later due to requirements of the judicial system.

According to Singer, the earliest medicolegal dissections took place at the University of Bologna, Italy, between 1266 and 1275. The first known postmortem examination on the American continent was performed in Hispaniola in 1533. In France, Ambroise Paré performed the first medicolegal autopsy in 1562, and the first autopsy performed in Eastern Europe was probably the one of King Stephen Báthory of Poland in 1586.

Our knowledge of the old autopsy procedures is rather scanty. With few exceptions, detailed written autopsy records exist mainly for relatively recent times. Such exceptions are reports on the autopsy of Emperor Maximilian II from 1576 and of Markgrave Jakob III of Baden. The latter died in 1590, at the age of 28, after a sudden illness that had lasted 9 days. A medicolegal autopsy was ordered and performed by two professors of the Freiburg University Faculty of Medicine. Their report pointed at poisoning by arsenic powder.

The principles of modern medicolegal investigation were developed based on the codes of sixteenth-century Europe: the Bamberg Code (*Constitutio Bambergensis*) in 1507, the Caroline Code (*Constitutio Criminalis Carolina*) in 1532, and later, the Theresian Code (*Constitutio Criminalis Theresiana*) in 1769.

The Austrian decree of 1855 contain very detailed instructions in 134 paragraphs as to the performance of medicolegal autopsy, and what is worth mentioning is that it is still today, a valid legislation in Austria. Similar, although not as detailed, is the Prussian edict of 1875. Both of these instructions can be considered as the culminating point of legislation dealing with the performance of medicolegal autopsy.

Clinical Autopsy

Clinical autopsy, as we understand it today, took much longer to develop and became meaningful first after the introduction of improved autopsy techniques and new concepts of pathogenesis of diseases by Carl von Rokitansky (1804–1878) and cellular pathology by Rudolf Virchow (1821–1902) (Figure 2).

Figure 1 The opening chapter of *De Abditis Nonnullis Ac Mirandis Morborum Et Sanationum Causis* – ‘The Hidden Causes of Disease,’ published in 1507 after the death of Antonio Benivieni (1443–1502).

Figure 2 Title page of the 4th Edition of Virchow's *Cellular Pathology* published in 1871.

In the beginning of the nineteenth century, increased attention was paid to the actual autopsy technique. Prost, a French physician insisted in 1802 that all organs of the body should be examined, and declared that 3 h was the minimum time for a postmortem examination. In 1846, Rudolf Virchow, then professor in Berlin, insisted on regularity and method and definitive technique. The classical techniques, which are still in use today, are more or less modifications of those introduced by Rokitansky, Virchow, Ghon, and Letulle, among others.

In 1872, Francis Delafield's *A Handbook of Postmortem Examination and Morbid Anatomy* was published in New York, and German and English editions of Rudolf Virchow's book on autopsy technique were published in 1876 (Figure 3).

The Present Use of Autopsy

Medicolegal Autopsy

Further development of medicolegal autopsy has been characterized and greatly influenced by the judicial system adopted in any given country, the main emphasis being on the detection and investigation of criminal and other unnatural or unexpected deaths. Due to different legislation and practices, there exists great variation in medicolegal autopsy rates between the countries. It is generally problematic to get access to this information, though some countries publish these figures regularly as background information on their mortality statistics. In England and Wales, some 230 600 (47%) deaths were reported to coroners in 2010. Of these, 44% involved a postmortem examination resulting in a coroner's autopsy rate of 20.6% of all registered deaths. The following medicolegal autopsy rates of all deaths for 2010 were available from Statistics: Norway (3.9%), Sweden (10.3%), and Finland (23.2%).

In addition to the national measures to create guidelines and to harmonize medicolegal autopsy, there has been an

Figure 3 Title page of the 4th Edition of Virchow's book on autopsy technique in 1893.

increasing international interest to achieve harmonized and internationally recognized rules on the way medicolegal autopsies should be carried out. This has become imperative, especially from the point of human rights as well as due to the increasing need for international collaboration in the investigation of mass disasters such as the 2004 Indian Ocean earthquake and Tsunami and the 2010 Haiti earthquake, both of which had an estimated death toll of over 220 000. These and the loss of thousands of human lives in various armed conflicts around the world should have made it quite clear to everyone, what implications a properly functioning medicolegal system, or the lack of it, may have upon society.

In May 1989, UN Economic and Social Council adopted in its resolution 1989/65 the Principles on the Effective Prevention and Investigation of Extra-Legal, Arbitrary and Summary Executions that had been created by cooperation with intergovernmental and nongovernmental organizations, especially the Minnesota Lawyers International Human Rights Committee. Later in 1991, the General Assembly of the United Nations endorsed the Model Autopsy Protocol of the United Nations.

European Council of Legal Medicine (ECLM) is an official body, registered according to the German law in Cologne, and deals with scientific, educational, and professional matters on European level. It has delegates nominated by the national medicolegal associations from all European Union and European Economic Space member countries. Since the early 1990s, the ECLM has been active in this field as well and its document 'Harmonisation of the Performance of the Medico-Legal Autopsy' was adopted by the General Assembly in London in 1995.

The Council of Europe is an intergovernmental organization which aims among others to protect human rights and pluralist democracy. It should not be confused with the European Union. The two organizations are quite distinct; however, all the 27 European Union states are also members of the Council of Europe, which currently has altogether 47 Member States. In its 43rd Ordinary Session, the Parliamentary Assembly of the Council of Europe adopted Recommendation 1159 on the harmonization of autopsy rules. Following this recommendation, a Working Party of international experts in legal medicine and law, with representation from the Interpol as well as the International Academy of Legal Medicine was established in 1996 under the Committee of Bioethics to make a proposal for Autopsy Rules. One of the guidelines used in the work was the Autopsy Rule produced earlier by the ECLM. The Working Party finished its work in November 1998 and this new Pan-European Recommendation No. R (99)3 on the Harmonization of Medico-Legal Autopsy Rules and Its Explanatory Memorandum were adopted by the Committee of Ministers on 2 February 1999, at the 658th meeting of the Ministers' Deputies. Although the document is a 'recommendation' by nature and hence strictly speaking not legally binding, it has, however, legal implications because all 47 Council of Europe member countries have agreed to implement these principles into their national legislations.

Many national authorities and professional organizations have created their own guidelines and standards, among others such as:

- The Code of practice and performance standards for forensic pathologists by the Home Office Policy Advisory Board

for Forensic Pathology and The Royal College of Pathologists, UK, November 2004, with additions, such as Guidelines on Autopsy Practice Scenarios for specific types of death, January 2005, and Coronial autopsies and current practice: Accuracy of cause of death and tissue sampling, November 2007.

- Forensic Autopsy Performance Standards by the National Association of Medical Examiners, USA, October 2005.
- Swiss Principles and Rules for Medico-Legal Autopsy by the Swiss Society of Legal Medicine, April 2007.
- Guidelines on Autopsy Practice for Forensic Pathologists, Criminally Suspicious Cases and Homicides by the Ontario Forensic Pathology Service, October 2007.
- The Code of Practice and Performance Standards for Forensic Pathologists dealing with Suspicious Deaths in Scotland by Scottish Government, COPFS, and The Royal College of Pathologists, November 2007.

Accreditation

Accreditation is a procedure by which an authoritative body gives formal recognition that a body or person is competent to carry out specific tasks: This aims to increase the credibility and acceptability of the reports and certificates issued by them. It is achieved by ensuring that the infrastructure, personnel, and the methods comply with preestablished criteria. The structure, processes, policies, and goals of the body to be accredited are described in a quality manual. Standard operating procedures have to be defined to describe the specific tasks that will be carried out by the entity. Recently, several German and Swiss institutes of legal medicine have been accredited by their respective national accrediting bodies regarding medicolegal activities including autopsies.

Clinical Autopsy

Despite the invent of more sophisticated investigative and imaging techniques, clinical autopsy has been shown to have maintained its value and remain an essential factor in the quality assurance of medical care. Regardless of this, there has been a progressive decline in autopsy rates throughout the world. The mandatory 20% autopsy rate required for accreditation of postgraduate training in the United States was withdrawn in 1971, on the grounds that each institution should set its own rate but that ideally should be close to 100%.

According to the World Health Organization (WHO) statistics published in 1998, the total autopsy rates varied in Europe in 1996 between 6% (Malta) and 49% (Hungary), and in other parts of the world reported to the WHO between 4% (Japan) and 21% (Australia). A more recent compilation of similar statistics is unfortunately not available. According to the WHO:

An assessment of the quality of cause-of-death information by WHO suggested that ideal systems operate in only 29 of 115 countries that report such statistics to WHO; these systems represent less than 13% of the world's population. In the remaining countries mortality statistics suffer from one or more of the following problems: incomplete registration of births and deaths, lay reporting of the cause of death, poor coverage and incorrect reporting of ages.

The reasons for this decline are many and complex: overreliance on the new diagnostic techniques, low appreciation of autopsy work, poorly performed autopsies by inexperienced trainees without proper supervision, long delay of autopsy reports, economical factors, fear of malpractice litigation, and so forth to name just a few.

The standardization and harmonization of clinical autopsy has taken place primarily at the national level. The quality of healthcare and quality assurance and audit has become increasingly important and has been introduced from laboratory medicine even for autopsies.

Objectives of Autopsy

An autopsy is a detailed systematic external and internal examination of a corpse carried out by a pathologist or one or more medicolegal experts to ascertain the underlying and possible contributing causes of death and, depending on the jurisdiction, also the manner of death. Before the pathologist can begin the examination, he/she must be sure that he/she has been authorized to perform the autopsy on that particular body. An assessment of possible risks that may be involved with the autopsy must be considered and necessary health and safety precautions taken. The autopsy and all related measures must be carried out in a manner consistent with medical ethics and respecting the dignity of the deceased.

An autopsy is performed to achieve one or more of the following objectives:

1. To identify the body or record characteristics that may assist in identifying the deceased
2. To determine the cause of death or, in the newborn, whether live birth occurred
3. To determine the mode of dying and time of death, where necessary and possible
4. To demonstrate all external and internal abnormalities, malformations, and diseases
5. To detect, describe, and record any external and internal injuries
6. To obtain samples for any ancillary investigations
7. To obtain photographs, videos, or, when appropriate and possible, use postmortem imaging techniques, and retain samples for evidential or teaching use
8. To provide a full written report and expert interpretation of the findings
9. To restore the body to the best possible cosmetic condition before the release

In addition to anatomical dissection, there are basically two main types of autopsy:

1. The clinical autopsy is to investigate the extent of a known disease and the effectiveness of treatment, and it is sometimes performed also for medical audit or research purposes. Almost invariably, the consent of relatives is needed unless the deceased has given the consent antemortem.
2. The medicolegal or forensic autopsy, which is ordered by the competent legal authority (a coroner, a medical examiner, a procurator fiscal, a magistrate, a judge, or the police), to investigate sudden unexpected, suspicious, unnatural, or

criminal deaths. Moreover, unidentified bodies or deaths occurring in special circumstances such as deaths in police custody or during imprisonment are often subjected to a medicolegal autopsy. In most jurisdictions, permission of the relatives is not required.

Autopsy Techniques

Both clinical and medicolegal autopsy may involve different strategies and techniques depending on the questions they are expected to answer. Autopsy technique in adults is generally somewhat different from pediatric autopsies.

The scope of medicolegal autopsy is much often broader than that of clinical autopsy and may include the investigation of the scene of death. All background information on the circumstances of death is of paramount importance for the choice of the right approach. In medicolegal autopsy, the examination of the clothing is often an essential part of the external examination, whereas in clinical autopsy, it is generally not. Both types of autopsies should consist of full external and internal examination of the body including the dissection and investigation of all three body cavities.

The external examination

- External description of the body includes the age, sex, build, height, ethnic group and weight, nutritional state, skin color, and other characteristics of the deceased such as scars or tattoos.
- Description of postmortem changes including all essential details relating to rigor mortis, hypostasis, and decomposition.
- Careful investigation and description of all body surfaces and orifices including color, length, density, and distribution of hair, color of irises and sclerae, presence or absence of petechiae or any other abnormalities or injuries. The examination should be carried out systematically and include head, neck, trunk, upper and lower extremities, and the back.

The internal examination

Examination of the body cavities include the description of the presence of gas (pneumothorax), fluids (effusions or exudates), or foreign bodies and the measurement of their volume, appearance of the internal surfaces and anatomical boundaries, as well as location and external appearance of organs.

The classical autopsy techniques vary mainly in the order in which the organs are removed:

1. The organs may be removed one by one (Technique of R. Virchow).
2. Cervical, thoracic, abdominal, and pelvic organs can each be removed as separate blocks (Technique of A. Ghon).
3. They may be removed as one single block, which is then subsequently dissected into organ blocks (Technique of M. Letulle).
4. All organs are dissected in situ (Technique of C. Rokitsansky).

All organs have to be dissected, the outer appearance as well as the cut surfaces described, and the weight of major organs recorded. The hollow organs have to be opened and their

content described and measured. All relevant vessels, arteries, and veins as well as ducts have to be dissected. All abnormalities must be described by location and size.

Sampling

Histological examination of the main organs should be performed in all autopsies. The need for further ancillary investigations may depend on whether the cause of death has been established with the necessary degree of certainty and, if not, additional samples have to be taken for toxicological or other investigations. For toxicology, this may include peripheral blood, vitreous humor, cerebrospinal fluid, bile, hair samples, or other relevant tissues. When retaining tissues, one has to take into consideration the possible restrictions depending on the national legislation.

Special procedures

Sometimes special procedures and modifications of normal dissection techniques are necessary. The stage at which radiology is employed in an autopsy will vary according to the individual circumstances and the most sophisticated techniques are available only for a very few. When available, computed tomography is the best technique for visualization of gaseous findings, such as air embolism, or when detecting gas accumulation in diving fatalities, or when locating foreign objects or skeletal trauma. Postmortem magnetic resonance imaging can be used to document soft tissue injuries in any kind of blunt trauma. Where neck trauma is suspected, the brain and the organs of the chest cavity have to be removed prior to the dissection of the neck to drain the blood from the area to avoid artifactual bleeding. Postoperative autopsies may present various problems with medicolegal implications, such as complications of anesthesia, surgical intervention, or postoperative care. However, detailed description of these special dissection procedures and techniques is beyond the scope of this presentation.

Autopsy Report

The report is an essential part of the autopsy. It should be full, detailed, and comprehensive. The medicolegal autopsy report, in particular, should be comprehensive even to the nonmedical reader. In addition to the factual, positive, and negative gross, microscopical, and analytical findings, the pathologist should conclude with a discussion on the significance of the findings. Where the findings are of uncertain nature and there are several competing causes, the pathologist should try to give an opinion as to their probability.

Brief Historical Introduction to Histopathology

After the first observations of animal and plant tissues in the early 17th century by Galileo, Hooke, Malpighi, and Leeuwenhoek, among others, using a newly invented instrument, the microscope, actual microscopic anatomy took a long time to develop. The father of modern histopathology, Marie-François Xavier Bichat (1771–1802), who was the first to introduce the systematic concept of tissues as distinct entities, did not use microscopy. René Théophile Hyacinthe Laennec (1781–1826), another famous French physician, was against the use of the microscope. Factors usually mentioned as obstacles to the scientific use of the microscope at this point were that it was surrounded by secrecy, the instrument was expensive, there were technical difficulties, and it was used by outsiders and lay people as a toy, and it only gradually found acceptance by the academia. According to Majno and Joris, the turning point was the perfection of the achromatic objective by J.J. Lister in 1830. Shortly thereafter, the microscope found its way into medical schools. It also took quite a long time until the millennia-old galenic theories about the pathogenesis of diseases were discarded and replaced by the modern concepts of cellular pathology in the second half of the 19th century. The first handbook of human histology for physicians and students by the Swiss anatomist Albert von Koelliker, who was, according to Garrison, “the most distinguished histologist of the early period,” was published in Leipzig in 1852 (Figure 1). von Koelliker was among the first to introduce the newer techniques of fixation, sectioning, and staining into microscopy. Probably the first official recommendation by a competent authority to use microscopy can be found in a Prussian decree on the procedure of medicolegal autopsy (1875), which recommended (§5) that the forensic doctor should have a microscope with two objective lenses and a minimum of 400-fold magnification. In his book about dissection techniques, Rudolf Virchow (1821–1902) also emphasized that, especially for medicolegal practice, certain pathological changes cannot be recognized by the naked eye but only with the help of a microscope or a magnifying glass.

Pathology/Histopathology as a Medical Specialty

Pathology exists as a medical specialty in most countries but there are differences as to the length and contents of the training as well as the number of subspecialties. In the United States, postgraduate training takes 4 years in the form of a pathology residency, after which the candidate can apply for certification either within Anatomical Pathology or Clinical Pathology or Combined Anatomical Pathology and Clinical Pathology, which are the primary specialties recognized by the American Board of Pathology. Subspecialty certification is

possible in Blood Banking/Transfusion Medicine, Chemical Pathology, Clinical Informatics, Cytopathology, Dermatopathology, Forensic Pathology, Hematology, Medical Microbiology, Molecular Genetic Pathology, Neuropathology, and Pediatric Pathology. The American Osteopathic Board of Pathology recognizes three specialty areas: Anatomic Pathology, Laboratory Medicine, and Forensic Pathology. In the United Kingdom, specialty training in Histopathology takes between 5 and 5.5 years to complete and takes place under the oversight of the Royal College of Pathologists and the General Medical Council. Within the European Union, the mutual recognition of medical specialties is regulated on the basis of the minimum period of training, which in Pathological Anatomy is currently 4 years, but varies from country to country, as seen in the case of the United Kingdom (Directive 2005/36/EC of the European Parliament and of the Council). This has significance mainly from the point of view of free movement of labor, that is, if the same specialty exists in two or more member countries, the specialist can move to practice his or her specialty in such a country without facing major bureaucratic issues.

Autopsy Histopathology

Medicolegal or forensic autopsy is performed at the behest and per the instructions of the legal authority responsible for the investigation of sudden and unexpected, suspicious, obscure, unnatural, occupational, litigious, or criminal deaths. Depending on the jurisdiction, the legal authority that decides whether medicolegal autopsy is necessary, may be a coroner, a medical examiner, a procurator fiscal, a magistrate, a judge, or the police; the systems vary considerably from country to country. Consent of relatives is usually not required.

It is often said that medicolegal autopsies are carried out in public interest, referring to the general welfare of the whole population. This expression is somewhat misleading and confusing because ultimately, in most cases, it is a question of the interest of an individual. Hence, the society or the legal authority is in a way representing the interest of the individual (s) because when the autopsy is ordered and carried out, there may be no knowledge about the person who will actually benefit or suffer from the results of the investigation.

Medicolegal autopsy often differs from hospital autopsy in so far as there may be no preliminary knowledge of the deceased or of either possible illnesses or circumstances of death, and the deceased may even be unidentified and just found dead. Therefore, the forensic pathologist ought to be prepared for every eventuality because presumed natural death may turn out to be practically anything, even a homicide. According to a survey by the Swedish National Board of Forensic Medicine (1994), approximately 8% of homicides in

Figure 1 The title page of the first edition of the first textbook of histology by Albert Kölliker (1817–1905) in 1852.

Sweden were detected first during medicolegal autopsy and according to another survey by Saukko, this occurred in about 4% of homicides in Finland. In principle, due to the possibility that results of a medicolegal autopsy may be used as evidence in a court of law, appropriate quality and procedural standards should apply at every step, as if it were a criminal investigation. Such a practice is rarely applied, unless it is obvious or at least suspected from the beginning of the investigation that the death is associated with a crime.

The International Code of Medical Ethics of the World Medical Association states: "A physician shall, in all types of medical practice, be dedicated to providing competent medical service in full technical and moral independence, with compassion and respect for human dignity." This means that the forensic pathologist should be able to independently decide,

for example, the extent of any ancillary investigations considered necessary. Although this is the case in some jurisdictions, there are others where there are restrictions due to the nature of the investigative procedure. The decision whether to carry out histological analysis may depend on the legal authority and not the pathologist: for example, in Germany, the public prosecutor in charge of the investigation of the medicolegal cause of the death in question decides what ancillary investigations (histology, toxicology, etc.) are necessary.

The starting point of autopsy histopathology is different from clinical histopathology in so far as the sampling usually takes place at least several hours or even days postmortem and the tissues can be altered by autolysis and putrefaction, whereas bioptic tissues or surgical samples can be processed immediately to minimize postmortem artifacts.

Forensic Histopathology

Forensic histopathology deals with assessment of histological findings in any forensically relevant context and their significance as forensic evidence, with the ultimate goal to serve proper administration of justice. It deals with basic phenomena such as postmortem changes in cells and tissues and their differentiation from vital changes, the timing and causes of injuries whether of mechanical or physicochemical origin, as well as exclusion or confirmation of any other pathological changes and their significance as possible underlying or contributing causes of death. In addition to the disease- and cause of death-related histopathology, questions may arise as to the human origin of tissue fragments when these have been recovered while investigating clandestine burial sites or in connection with mass disasters or whenever there is a need to establish personal identity from any tissue by applying molecular biological methods. Occasionally, the question of kinship may arise first after the death and autopsy of a putative parent. In case tissue has been retained for histology, formalin-fixed, paraffin-embedded tissue blocks can be used for DNA extraction to investigate the issue.

Quality

The earlier mentioned Prussian decree on the procedure of medicolegal autopsy (1875) and its recommendation to use microscopy imply that, even in those early days of histopathology, the necessity for high standards and quality in medicolegal investigations was fully recognized. However, it took quite some time before the idea of quality control, quality assurance, and audit found its way into medicine. Although the necessity of quality systems is now better understood, there are significant regional, national, and individual differences in the standard of practice. As Cordner has pointed out, "The major change that has occurred in the last 20 years in considering autopsy quality is that the autopsy must be reviewable." Without a full histological survey this is not feasible. Quality also depends on the standards of specialized education, continuing professional development, and harmonization of investigative procedures, which are still far from being uniform.

Guidelines

Guidelines usually represent recommendations allowing some variation in practice. The most recent trend, particularly in the medicolegal field, seem to be moving toward accreditation that necessitates the introduction of standardized operational procedures. Accreditation procedures have usually been applied to calibration and testing laboratories but the European Network of Forensic Science Institutes and European Cooperation for Accreditation, the European network of nationally recognized accreditation bodies located in the European geographical area, are currently working on a joint project aiming to define which standard, ISO/IEC 17020 or ISO/IEC 17025, is to be used for the different forensic fields.

Currently, many autopsy guidelines express a view on autopsy histology.

A recommendation of the Council of Europe: Rec (99) 3 of the Committee of Ministers to Member States on the harmonization of medicolegal autopsy rules, adopted by the Committee of Ministers on 2 February 1999, states in Section 6 Sampling: "the following minimum rules should be applied:

- a. in all autopsies, the basic sampling scheme includes specimens from the main organs for histology."

The Royal College of Pathologists (United Kingdom) *Guidelines on Autopsy Practice*, September 2002, takes a similar position in Section 9 Autopsy histology:

9.2. As best practice, sampling of all major organs for histology in all autopsies is recommended.

And further emphasizing the importance of histology to the cause of death investigation:

9.6.2. If in advance of the autopsy, discussions with a Coroner indicates to the pathologist that retention of material that may be relevant to the investigation will not be permitted, the pathologist should decline the request to perform the autopsy.

The Code of Practice and Performance Standards for Forensic Pathologists by the Home Office Policy Advisory Board for Forensic Pathology and The Royal College of Pathologists, November 2004, and Code of Practice and Performance Standards for Forensic Pathologists dealing with Suspicious Deaths in Scotland by the Scottish Government, COPFS, and The Royal College of Pathologists, November 2007, have the same standpoint toward postmortem histology:

A histological examination of the major organs (assuming that they are not heavily decomposed) should be made by the pathologists themselves in all suspicious deaths. Histology is of value in confirming, evaluating, and sometimes revising the course of natural disease processes that may have contributed to the cause of the death. Other samples should be taken for histological examination depending on the circumstances of the case, for example, for the purposes of ageing injuries. The reasons behind any decision not to undertake a histological examination must be adequately recorded, in order that the pathologist may be in a position to defend this decision if required.

The Ontario Forensic Pathology Service: Practice Manual for Pathologists (October 2009, Version 2.0) states:

In Section 1.11. Histology and ancillary tests: "If death has occurred due to a natural condition, histology should be used to provide reviewable documentation of the lethal disease/lesion," and in Section 2.6. Histology, ancillary testing, and consultations: "Routine histology and toxicology are performed in all homicide and criminally suspicious cases, as determined by the state of the body."

Methods

Sampling

Sampling of tissues has to be carried out in a systematic manner from obvious or suspected pathological findings, or when no such pathology is seen, representative samples should be

taken from all main organs. Special sampling protocols and procedures have been recommended by various authors and/or professional organizations and may apply, for instance, in sudden cardiac deaths, in pediatric cases such as sudden infant death syndrome/sudden unexpected death in infancy, or sudden death in epilepsy (SUDEP). Sites from which the samples have been taken should be appropriately recorded in the autopsy protocol to ensure topographical correlation and comparison with macroscopical findings and possible later review and quality assurance measures. In all medicolegal cases involving specimens for histology, they should be identified on receipt, matched with request forms, and receive an accession number to guarantee an unbroken chain of evidence accounting for the handling and processing of each sample from the moment of its appropriation. Specimens should be handled with care. When trimming the tissues for fixation or embedding, they should be cut with sharp instruments in order to avoid artifactual changes.

Fixation

Tissue specimens can be used as frozen fresh tissue that is cut using a cryostat or autolytic processes and bacterial degradation can be stopped and the proteins stabilized by chemical fixation. The choice of the optimal fixation method depends on the staining methods. For routine histopathology, most tissues are fixed using buffered formaldehyde. The size and the thickness of the specimen must be in correct proportion to the chosen fixative and appropriate fixation time to avoid fixation artifacts. Special methods such as immunohistochemistry may necessitate shorter fixation times than classical histochemistry, as too long a fixation may destroy the antigenic properties of the tissue and produce false-negative results. Special procedures are often necessary for enzyme or immunohistochemical methods or to demonstrate substances that are easily inactivated, destroyed, or removed during routine fixation or tissue-processing procedures. After fixation, the tissue samples are processed either manually or using automated tissue processors, dehydrated, and embedded in paraffin wax to allow them to be cut into thin sections with a microtome (usually 4–7 μm) for light microscopy. In transmission electron microscopy, samples are usually embedded in epoxy resin and cut with an ultramicrotome into ultrathin sections that are stained using heavy metals such as lead, uranium, or tungsten.

All stages of specimen handling – embedding, cutting, and staining – and the choice of materials are important and contribute to the final result, and each of them can be a potential source of artifacts that may endanger the correct interpretation of the findings.

Staining

The tissue sections are mounted on a glass slide and can be observed in their native form, for example, to detect foreign bodies such as asbestos in the lungs, but usually they are stained using various techniques to provide better contrast by natural or synthetic dyes or by complementary enzyme or immunohistochemical staining methods, depending on the purpose. The affinity of tissues to a given stain depends on complex physicochemical interactions between the solvent,

dye, and tissue. Due to their characteristic affinity to different tissue components, the dyes help to recognize morphological features of normal tissue and to differentiate them from pathological changes. Injured tissue may show an altered affinity to a given stain, for instance, increased cytoplasmic eosinophilia resulting from increased binding of eosin by cytoplasmic proteins with hematoxylin–eosin stain as seen, for example, in ischemic neurons in the brain or in myocardial injury. Many of the classical staining methods, such as hematoxylin–eosin, Mallory's phosphotungstic acid–hematoxylin, or van Gieson stain, among others, were introduced in the nineteenth century and are mainly used to visualize morphological changes in the cells and tissues; many of them are still in use today.

Special techniques are used to demonstrate specific components such as iron in cells or tissues. In Perls' Prussian or Berlin blue reaction (Max Perls, 1843–81), the section is treated with dilute hydrochloric acid to release ferric ions from binding proteins. These ions will react with potassium ferrocyanide to produce an insoluble blue compound. Fats or lipids have to be stained using frozen sections as fixation and tissue processing usually remove them (Oil-red-O or Sudan stain).

Microorganisms, such as *Mycobacterium tuberculosis*, can be demonstrated using Ziehl–Neelsen stain or bacteria using Gram stain. Periodic acid–Schiff or PAS stain can be used to stain fungi. It also stains glycogen, mucin, mucoprotein, and glycoprotein. Viral antigens can be detected using immunohistochemistry by specific, typically monoclonal, antibodies against viral protein generated in laboratory animals. The sensitivity and specificity vary according to the type of the virus (Figure 2).

In 'in situ hybridization,' a labeled viral DNA or RNA probe is used to localize a specific DNA or RNA sequence of the virus within a tissue section.

Enzyme histochemical methods were used in the 1960s and 1970s particularly in animal experiments and also to some extent for diagnostic purposes on autopsy material. As routine fixation and subsequent tissue processing destroy or diminish the enzyme histochemical reactivity of most enzymes, cryostat sections from fresh frozen tissue have to be used. Enzyme

histochemical methods are usually named after the individual enzymes, implying that the method might indicate the biochemical activity of the enzyme in question. However, the enzyme histochemical reactivity does not necessarily correlate with the actual biochemical activity of the enzyme in question, suggesting that other factors, such as the presence of auxiliary enzyme systems or other cofactors of the histochemical reaction, may be rate-limiting. Therefore, these methods also need to be validated accordingly before they can be applied to diagnostics in the medicolegal context.

Some conventional histological methods, such as acid fuchsin or hematoxylin-basic fuchsin-picric acid stain, where a shift in color was claimed to indicate early myocardial ischemia, have been shown to be unreliable for such diagnostic purposes.

The advances of immunohistochemistry and the availability of a large number of new antibodies have made the use of immunohistochemical methods common even in medicolegal problems, in particular in the context of vitality and aging of wounds, head injury, and early myocardial injury. So far, the results have been difficult to assess because of diverse findings and sometimes also because of shortcomings in the experimental design and control material. It is obvious that in experienced hands with well-established and properly validated methods, immunohistochemistry can be of advantage over conventional histochemistry.

Histopathological Diagnosis

Histopathological diagnosis is the result of a complex cognitive process requiring knowledge and experience, attention, and recognition of the characteristic features necessary to identify the disease process in question. This can be achieved either by recognition of purely morphological changes in tissues or cellular structures, such as loss of structural elements like cerebellar Purkinje cells in chronic alcoholism, deposition of abnormal proteins in tissues such as amyloid in cardiac amyloidosis, or invasive growth of tissue as in malignant tumors or infiltration and destruction of normal tissue elements by inflammatory cells as in infections caused by microorganisms, to name a few examples. Furthermore, the observed histopathological changes need to be assessed for their significance as a possible cause of death. The correctness of the results can be further influenced, in addition to the intellectual factors, by methodological issues and individual working habits such as sampling rate (a low number of samples decreases the probability of hitting focal lesions such as seen, for example, in myocarditis), the use of correct fixation and staining methods, and proper positive and negative controls when appropriate, particularly when applying immunohistochemical methods.

Histological Findings as Forensic Evidence

The knowledge of the significance and evidential value of histological data is essential for the administration of justice. However, there are few controlled studies on the reliability of histological diagnoses in the forensic context. In an unpublished

survey, we assessed the frequency of myocarditis diagnoses by 20 forensic pathologists during a 10-year period in Finland, comprising over 70 000 medicolegal autopsies. When correlating the frequency of such diagnoses with the overall frequency of histology taken in postmortems by the same pathologists, there were obvious discrepancies concerning some individual pathologists showing, for example, a high and above-average frequency of myocarditis diagnoses although the overall frequency of histology sampling was significantly below average. This led to a study where all death certificates with myocarditis recorded as the underlying cause of death in Finland from 1970–98 were collected retrospectively. All cases with cardiac autopsy samples and clinical data available ($n=142$) were included and the cardiac samples were reexamined. The histopathological reanalysis showed that only 32% of the 142 subjects met the Dallas criteria for myocarditis. The most evident cause of death in the Dallas-negative subjects was ischemic heart disease (IHD) ($n=78$, 55% of all cases), suggesting that myocarditis is overdiagnosed in routine autopsies, particularly in patients who have died suddenly or are found dead.

According to Janssen, the significance and evidential value of histological data can be approached and discussed from the following aspects: “first, according to the evidential value of the tissue data itself; second, according to its position within the framework of evaluation which results from the facts of the case that have come to light in combination with other findings.” He further grades the evidential value of forensic histology results in to three groups (slightly modified from Janssen 1984):

Group 1: Comprises histological findings where identification of their cause, character, and chronological pathogenesis is definite, permitting conclusions about the etiology and causality independent of any further data, for example, in certain stages of tuberculosis and foreign-body granulomas (Figure 3).

Group 2: Comprises findings that have forensically verifiable significance in association with further premises. The

Figure 3 Microscopic view of a small foreign-body granuloma (arrow) in polarized light showing birefringent material from the use of adulterated drugs, within the pulmonary vessel wall of an intravenous drug addict.

Figure 4 Malignant brain tumor (astrocytoma) detected first by microscopy in a victim of sudden unexpected death.

presence of additional facts is, therefore, a prerequisite for the conclusiveness of such evidence.

Janssen describes as an example, suspected homicide by means of an assault to the neck where isolated fresh hemorrhages in the deep soft parts of the victim's neck can be considered as evidence of strangulation only in combination with corresponding injuries of the overlying skin and larynx and further indications of asphyxiation and vascular congestion. As such, the hemorrhages alone are not unequivocal and not of conclusive significance.

Group 3: Comprises findings that neither singly nor in combination with other facts represent evidence that excludes all other possibilities of causal explanation. Examples are: acute vascular congestion, pulmonary emphysema, petechial serous hemorrhages, cerebral edema, and the majority of all parenchymal necroses. Janssen considers these findings either inappropriate or only of limited use as forensic-histological proof.

Problem Areas

In those jurisdictions where sudden, unexpected natural deaths belong to the domain of forensic pathologists, these may comprise around half of the autopsy workload. The majority of these, at least in industrialized countries, are usually due to IHD, the reliable diagnosis of which is still a diagnosis per exclusion as sclerosis and stenosis of coronary arteries as such are not sufficient to diagnose sudden cardiac death. Early morphological changes of injury, as seen in light microscopy, are unspecific, and even a fresh myocardial infarction visible to the naked eye does not necessarily prove that the person died because of it (Figure 4).

Other problematic areas where special expertise and methodology are necessary are, for example, deaths associated with medical investigative or therapeutic procedures, head injury, SUDEP, and pediatric forensic pathology where a forensic neuropathologist or forensic pediatric pathologist should be consulted and involved at an early stage of investigation (Figure 5).

Figure 5 A 4-year-old girl was found dead in her bed. Cerebellar Purkinje cells show fibrinogen immunoreactivity (black arrow pointing at one of the seven positive cells) suggesting breakdown of the blood-brain barrier and leakage of plasma fibrinogen in probable sudden death in epilepsy (SUDEP).

Special medicolegal questions such as the timing of injury necessitate solid expertise from the pathologist and properly validated methodology and should preferably be based on experimental research and proved in practical casework.

Considering the high requirements for the reliability of forensic evidence, it is essential that histological examination is an integral part of every autopsy. There are studies that have reported that histology brings new evidence in only a given percentage of cases. This may be correct but one should be aware that all such cases have been identified in hindsight and it is practically impossible to know in advance with any certainty what might be the result in the particular case now under investigation. New questions may arise afterward and may remain unanswered if histology samples have not been taken. An autopsy is not complete and reviewable without histology and both sampling and microscopy should preferably be in the same hands and carried out by the same pathologist who performed the autopsy.

Early and Late Postmortem Changes

Introduction

Dying and death are continuous final biological processes that have been undefined for a long time. In his work on contemporary Roman law, the well-respected nineteenth-century jurist Friedrich Carl von Savigny wrote that death represents such an elementary and natural event that has no need for closer definitions of its elements. It was not until the introduction of machines to take over circulatory or respiratory functions that the need for a legal definition of death arose, such as would protect a physician from judicial prosecution (e.g., turning off of life-support systems). Today, the accepted criteria for death are irreversible cessation of respiratory or circulatory functions, or determination of brain death following serious primary or secondary brain damage, where, in the case of brain death, functioning of the cerebrum, cerebellum, and medulla oblongata has ceased.

Supravitality

Irreversible circulatory or respiratory arrest is the main criterion for death, followed by early postmortem changes, lividity, and rigor mortis. However, metabolism of tissues does not cease immediately after death but continues for some hours. Supravitality is the survival of tissues under global ischemia. Supravital reactions are reactions of tissue on excitation which are much like those during life. The supravital period is specific for each tissue, depending on specific metabolisms (enzymes, substrates) and local temperature. The main energy-producing metabolic processes in the early postmortem period are the creatine kinase reaction and anaerobic glycolysis. Studies on global ischemia in various organs focus mainly on organ preservation and organ transplantation. The latency period is defined as an undisturbed time interval characterized by continuing aerobic energy production. The survival period is the interval to the point following which every aspect of life ceases. During the survival period, there may be spontaneous activity of organs (e.g., instantaneous but decreasing myocardial contractility), and also reactivity (e.g., response of muscles to stimulation). The resuscitation period is defined as the duration of global ischemia after which the ability to recover expires. The resuscitation period mainly comprises the interval when complete recovery of morphological, functional, and biochemical parameters in the postischemic period is still possible. Some supravital reactions are of great practical importance in forensic medicine as they can easily be examined at the scene of crime and provide immediate results on the time elapsed since death: these are mechanical and electrical excitability of skeletal muscles and the pharmacological excitability of the iris.

Mechanical Excitability of the Muscle

The mechanical excitability of skeletal muscle is examined by rigorously hitting a muscle with the back of a knife or a chisel, for example, the biceps brachii muscle, in a perpendicular direction; other muscles can be examined as well but reference figures for estimating the time since death are available for the biceps brachii muscle only.

Electrical Excitability of the Skeletal Muscle

In the early postmortem interval, excitation causes strong contraction of muscles including those distant from the electrodes, while with increasing postmortem interval, contraction will become weaker and muscular response will be confined to the excitation location, a reaction pattern intensely involving more or less all muscles. Finally, only fascicular twitching or movement of the electrodes will be visible. The most extensive investigations have been carried out on orbicularis oculi muscles as its movements are easy to identify. For the orbicularis oculi muscle, needle electrodes are inserted in 15–20 mm distance into the nasal part of the upper eyelid at 5–7 mm depth. The muscular response is graded into six stages (Figure 1). In the very early postmortem stage (degree VI), the whole ipsilateral muscle will contract, whereas in degree V, only the upper and lower eyelid and forehead will respond. With increasing postmortem interval, reactions will be confined to the excitation location.

For stimulation, a small square wave generator producing constant current rectangular impulses of 300 mA at 10 ms duration is used at a repetition rate of 50 ms (producer and supplier: Peschke J, <http://home.t-online.de/home/j-peschke/rztg1.htm>).

Pharmacological Excitability of the Iris

Compared to skeletal muscles, the smooth iris muscle is irritable by electrical and pharmacological stimulation for a much longer period of time. In some cases, excitability by subconjunctival injection of noradrenaline or acetylcholine may persist up to 46 hpm.

Postmortem Lividity

After irreversible circulatory arrest, postmortem lividity develops as the earliest postmortem change. Following circulatory arrest, hydrostatic pressure becomes the leading force within the parallelogram of forces comprising blood pressure, structural barriers, tissue turgor, and pressure from underlying

surfaces. Hypostasis means the movement of body fluids according to gravity. All compartments are involved in hypostasis, not only intravascular but transcellular fluids as well. Influenced by gravity, blood moves to the lowest parts within the vascular system; in a supine position, it flows to the back, buttocks, thighs, calves, and back of the neck. Irregular facial pink patches, especially over the cheeks in the agonal period, are caused by local stasis. Postmortem cutaneous lividity is a consequence of movement of blood into capillaries of the corium. It may appear 20–30 min postmortem, still as pink patches in the early stages becoming gradually confluent with increasing postmortem time. Due to consumption of oxygen, the color changes from pink to dark pink or bluish.

In areas of intense hypostasis, cutaneous petechial hemorrhages due to capillary ruptures, called vibices, may develop. It is not only the development of lividity or of color that is of diagnostic and criminalistic relevance, but also its distribution, as well as the phenomena of fixation

(disappearance after turning the body) and disappearance (blanching) on blunt/thumb pressure.

In case of carbon monoxide poisoning and cyanide toxicity, the color of hypostasis is typically cherry pinkish, while methemoglobin intoxication is brownish. Due to lack of dissociation of oxygen from hemoglobin, a bright pink color may be seen in hypothermia as well. In a body transferred from a cold environment into normal room temperature, typical zonal segmentation of hypostasis may be seen with a dark bluish color in the rewarmed areas.

Of predominant criminalistic significance are the phenomena of disappearance on pressure and disappearance of lividity after turning the body. In the early stages, lividity will completely disappear on soft thumb pressure, but with ongoing postmortem interval, the pressure also has to increase. Later, lividity will disappear only incompletely on pressure and finally it will not disappear at all.

If the body is turned in the early postmortem interval, some or all of the hypostasis may move to different areas. In a comparatively later postmortem interval, only some of the hypostasis will migrate down to new areas and only slight blanching will be noted in the original region.

With increasing postmortem time, disappearance of lividity on thumb pressure and relocation after shifting decreases, and then ceases completely.

The best statistical data available for the different criteria of lividity were summarized by Mallach, who calculated mean values, standard deviations, and 95% limits of confidence based on textbook reports (Table 1). As better data are still missing, these data are still undisputed. However, it should be kept in mind that these data do not represent absolute thresholds. Investigations based on quantitative measurements of livor mortis have not yet gained practical importance.

Figure 1 Six degrees of positive reaction after stimulation of the orbicularis oculi muscle (see also Table 1).

Rigor Mortis

The second postmortem change and sign of death, developing in normal ambient temperature about 3–4 h postmortem after primary flaccidity, is rigor mortis, which was misinterpreted as the sign of death until the nineteenth century although

Table 1 Time course of different criteria of lividity. Statistical calculations by Mallach based on textbook reports. The statistical calculations are not based on cross-sectional or longitudinal studies but on empiric knowledge quoted in textbooks. $\bar{x}$ = mean value; s = standard deviation

	$\bar{x}$	s	$2s$		Range of scatter		Number of quotations
			Lower limit	Upper limit	Lower limit	Upper limit	
Development	$\frac{3}{4}$	$\frac{1}{2}$	–	2	$\frac{1}{4}$	3	17
Confluence	$2(\frac{1}{2})$	1	$\frac{3}{4}$	$4(\frac{1}{4})$	1	4	5
Greatest distension and intensity	$9(\frac{1}{2})$	$4(\frac{1}{2})$	$\frac{1}{2}$	$18(\frac{1}{4})$	3	16	7
Displacement							
1. Complete on thumb pressure	$5(\frac{1}{2})$	6	–	$17(\frac{1}{2})$	1	20	5
2. Incomplete on sharp pressure (forceps)	17	$10(\frac{1}{2})$	–	$37(\frac{1}{2})$	10	36	4
Displacement after turning the body							
1. Complete	$3(\frac{3}{4})$	1	2	$5(\frac{1}{2})$	2	6	11
2. Incomplete	11	$4(\frac{1}{2})$	$2(\frac{1}{4})$	20	4	24	11
3. Only little pallor	$18(\frac{1}{2})$	8	$2(\frac{1}{2})$	$34(\frac{1}{2})$	10	30	7

Shakespeare (*Romeo and Juliet*, Act. IV, Scene 1) described all elements of rigor mortis very well:

Each part, deprived of supple government, shall, stiff and stark and cold, appear like death.

With irreversible circulatory arrest, all muscles will become completely flaccid due to loss of tone. In the early postmortem interval, adenosine triphosphate (ATP), the biochemical source of energy, can be resynthesized via the creatin kinase reaction and anaerobic glycolysis. Once the ATP level has fallen below 85% of the initial value, actin and myosin filaments form a complex which is not split so that the muscle remains inextensible. Development and state of rigor mortis are proven subjectively by bending a joint: either the muscles are flaccid or during development of rigor mortis some resistance may be noted. If rigor is fully developed, even a strong examiner cannot flex or stretch a joint.

Rigor must not be mixed up with cold stiffening. When rigor is present, hypostasis must be present as well, whereas in cases of cold stiffening (body core temperature 30–33 °C), hypostasis is absent.

The development and state of rigor should be examined in several joints (mandibular joint, finger, knee, elbow) to assess whether it is still in progress or has already reached its maximum.

Rigor mortis does not commence in all muscles simultaneously. Nysten's rule (1881) that rigor starts in the mandibular joint, muscles of the trunk, then in the lower, and lastly in the upper extremities applies to most cases with dying in a supine position. However, in cases with glycogen depletion during agony in the lower extremities, rigor will commence there.

Dissolution of rigor mortis is due to protein degradation (increase of ammonia, NH_3).

As in different fibers of a muscle, rigor does not start simultaneously but successively; this phenomenon can be used for a rough estimation of the time since death as well. If some of the fibers have already become stiff, this stiffness can be broken by bending a joint; rigor may now develop in other, not yet

stiffened fibers. Depending on the time when stiffness has been broken, rigor may develop again on a higher or lower level unless it was already fully developed (Figure 2). This phenomenon of reestablishment of rigor mortis may be seen up to 6–8 h postmortem, and in very low ambient temperatures up to 12 h postmortem.

Secondary flaccidity of muscles may become apparent in normal ambient temperature after 2 days. In low ambient temperatures, fully developed rigor mortis may linger for 2 weeks and longer.

Cadaveric rigidity, cataleptic spasm, or instantaneous rigor are names for a phenomenon that is always mentioned in textbooks but nonexistent in practice. Not a single case reported in the literature withstands criticism.

Rigor mortis can be found not only in skeletal muscles but also in smooth muscles, for example, the skin. Rigidity of the smooth muscoli arrectores pilorum can be seen as goose pimples (*cutis anserina*).

Development, duration, and dissolution of rigor mortis depend on the amount of glycogen in the muscle at the moment of death, ambient temperature, and other factors.

Therefore, rigor may develop very fast in persons who die close to exhaustion due to physical exertion or from electrocution. All of the criteria of rigor mortis mentioned earlier (e.g., development, reestablishment, full development, duration, resolution) are time dependent. This was already evident from one of the rare studies from the nineteenth century on rigor mortis. Niderkorn, who determined the time necessary for the completion of rigor mortis in 113 bodies, found it fully established after 4–7 h in 76 corpses (67%). In two cases, rigidity was complete within 2 h postmortem, and in two others, within 13 h postmortem.

However, interindividual variability from endogenous and exogenous factors covers a wide range. Longitudinal studies on large random samples are missing; however, a number of animal experiments taking into account various factors influencing the time course of rigor mortis have been published. Devices for objective measurement of rigor mortis have been developed but have not yet gained practical importance.

Figure 2 Reestablishment of rigor mortis after breaking. The later rigor during development of rigor mortis is broken, the lower will be the level after reestablishment. If rigor is broken after it has already been fully developed (F), it will not be reestablished at all.

Table 2 Time course of different criteria of rigor mortis according to the calculations by Mallach based on textbook reports

Rigor state	Average hours postmortem and standard deviation	Range of scatter in hours (2s)		Number of quotations
		Lower limit	Upper limit	
Beginning	3 ± 2	–	7	26
Maximum	8 ± 1	6	10	28
Duration	57 ± 14	29	85	27
Complete resolution	76 ± 32	12	140	27

The best available data despite all justifiable criticism originate again from Mallach, based on the compilation of literature (1811–1969) with statistical analyses (Table 2). These figures again cannot claim to be absolute limit values. Like lividity, rigor mortis can give only a rough estimate and no high accuracy can be expected. It never should be examined isolated.

Algor Mortis, Postmortem Body Cooling

If the ambient temperature is lower than the body core temperature (normally 37.2 °C), the body temperature will decrease postmortem. The postmortem drop of the body temperature results from four factors: convection, conduction, radiation, and evaporation, the first two being the leading causes.

Postmortem heat production is low as anaerobic glycolysis ceases within a few hours postmortem. Convective heat transport within the body stops with circulatory arrest. Heat exchange is then mainly based on conduction. The conductive heat transport within the body is mainly due to temperature differences of neighboring tissue layers. As the heat conductivity of body tissues is rather low, conductive heat transport within the body proceeds slowly.

The rate of cooling depends on various conditions and varies with several factors:

- ambient conditions (temperature, wind, rain, humidity)
- weight of the body, mass/surface area ratio
- posture of the body (extended or thighs flexed on the abdomen)
- clothing/covering

In case of temperature differences between body center and surface or body surface and surrounding temperature, heat transport basically takes place radially, from the axial center of the body to the surroundings. Postmortem cooling of core temperatures (e.g., rectal temperature) is best represented by a sigmoid curve comprising three phases (Figure 3).

- initial phase, the so-called temperature plateau or lag period during which the body temperature remains relatively constant
- intermediate phase, with a rapid drop of the body temperature
- terminal phase, in which the drop slows down continuously as the core temperature approaches that of the environment

Figure 3 Sigmoid shape of the cooling curve, which is best described by Marshall and Hoare's two-exponential term. The quotient $(T_r - T_a) / (T_0 - T_a)$ is a good measure of the progress of cooling. If this quotient Q is < 0.3 , only a minimum interval of the time since death should be given. T_0 , rectal temperature at death ($T = 0$); T_r , rectal temperature at any time, and T_a , ambient temperature.

The postmortem temperature plateau is mainly determined by physical preconditions as it is due to the fact that central axial temperatures cannot begin to decrease until a heat gradient is set up between the core of the body and its surface. This delay is variable and may last for some hours.

Its duration depends on the same influencing factors as the exponential cooling curve following the plateau (radius, radial position of measuring site, cooling conditions). The shorter the temperature plateau, the steeper the curve drops away.

The postmortem temperature plateau causes a sigmoid shape of the cooling curves at any site of measurement far from the surface. It is a combined effect of the postmortem temperature plateau followed by single exponential cooling according to Newton's law.

Different temperature probe sites were used (surface skin temperature, axilla, liver, rectum, brain temperatures); for practical purposes, only central core temperature. Authors in the nineteenth century, using rectal temperatures, described a lag time, the postmortem temperature plateau, before exponential body cooling according to Newton's law commences (Figure 3).

A mathematical expression of rectal cooling after death was published by Marshall and Hoare, taking into account the sigmoid shape of the cooling curve. They performed experiments under 'standard conditions of cooling' which were defined as 'naked body with dry surfaces, lying extended on a thermally indifferent base, in still air.' Their mathematical model was expressed in a two-exponential term:

$$Q = \frac{T_r - T_a}{T_0 - T_a}$$

$$A \exp(Bt) + (1 - A) \exp \frac{(AB)}{A - 1} t$$

where Q = standardized temperature; T_r = rectal temperature at any time t ; T_o = rectal temperature at death ($t=0$); T_a = ambient temperature; A = constant; B = constant; t = time of death.

The second exponential term is subtracted from Newton's exponential term taking into account that temperature plateau is from zero, increasing temperature decrease.

This mathematical expression is valid for all central axial temperatures and represents the ultimate success in modeling body cooling for the purposes of estimating the time since death.

The exponential form with the constant B expresses the exponential drop of temperature following the plateau according to Newton's law of cooling; the term with the constant A as part of the exponent describes the postmortem temperature plateau.

The experimental work which led to an identification of these constants is outlined in several original papers and two monographs, which are referred to here.

With this empirical solution of Marshall and Hoare's formula, the time since death can be computed either according to

$$Q = \frac{T_r - T_a}{37.2 - T_a} = 1.25 \exp(Bt) - 0.25 \exp(5Bt)$$

(for ambient temperatures up to 23 °C) or

$$Q = \frac{T_r - T_a}{37.2 - T_a} = 1.11 \exp(Bt) - 0.11 \exp(10Bt)$$

(for ambient temperatures over 23 °C)

using computer programs developed by Henssge or using a nomogram (Figure 4).

The nomogram is valid for the chosen standard conditions of cooling (naked body with dry surfaces, lying extended on a thermally indifferent base, in still air). Conditions which accelerate or delay body cooling compared to standard conditions (e.g., deposition in water, wind on the one hand, clothing, covering on the other) theoretically reduce or increase the real body weight. Extensive cooling experiments under varying cooling conditions led to empiric corrective factors for the body weight (Table 3). With these the nomogram can also be used for nonstandard cases. The corrective factors themselves depend on the body weight in case of low and/or high body weights under higher thermic insulation conditions. Higher body weights need lower factors and, vice versa, lower weights require higher factors. The nomogram can also be used in cases of sudden changes of ambient temperatures.

From all methods developed to estimate the time since death, the nomogram method based on the double exponential term by Marshall and Hoare is by far the most successful and reliable one because

- Actual cooling conditions can be taken into consideration quantitatively.
- Data on the precision of the method are available.
- Field studies have confirmed the accuracy and reliability of the method.

Postmortem Changes

Due to their time sequence, the early signs of death in a cadaver (rigor mortis and livor mortis), along with the supravital reactions, are today instrumental in accurately determining the postmortem interval (i.e., the time elapsed since onset of death). Immediately following the early signs of decay, the later stages begin. These cannot be separated strictly chronologically. They lead not only to decomposition of the cadaver, but in some cases also to its preservation. Different exogenous and endogenous factors contribute to destruction and decomposition of a corpse. Among endogenous factors are autolysis, putrefaction, and decay, while exogenous factors include animal predation, exposure to the elements, and mechanical injury.

Onset and extent of postmortem changes are influenced by many extrinsic and intrinsic factors (Table 4).

Various dissimilar signs of advanced decay may appear simultaneously in a cadaver resulting from changes to the surrounding conditions. If a corpse is exposed due to its position to different environmental conditions (such as lying in a roadside ditch, half-submerged in water, half-exposed to air), varying processes of decay may occur simultaneously.

Autolysis (Self-digestion)

Autolysis is defined as the destruction of an organ's structures by its own enzymes. Organs, such as the pancreas, which are already rich in enzymes in life are thus subject to very quick self-digestion after death. Under convenient circumstances, for example, when a cadaver is stored at high temperatures, only a few hours are required to render a histological diagnosis of the organ itself impossible. Due to the effects of gastric acid, autolysis of the stomach lining occurs relatively quickly, possibly leading to complete softening. The adrenal medulla is also destroyed quite rapidly.

Putrefaction

Contrary to autolysis, putrefaction described as a 'heterolytic' alkaline colliquative process on a reductive basis caused by bacteria, displays typical characteristics while progressing, both visual (bloating) and olfactory (foul ammoniacal odors), due to the production of gases (hydrogen sulfide, hydrocarbons) and the release of ammonia. Body parts particularly affected by bloating from gas accumulation are all tissues with a low turgor ('liquid' pressure from within), such as eyelids, mouth, and tongue, which may become monstrously swollen. The abdomen may also become extremely swollen due to gas accumulation. Gas production is the main reason for drowned bodies soon floating at the water surface. The abdominal wall shows a greenish discoloration, resulting from production of sulfhemoglobin as oxygen is used up by intestinal bacteria. As this process requires oxygen, the green discoloration caused by sulfhemoglobin accumulation first appears over those parts of the body where the intestines lie closest to the abdominal wall, such as the lower right abdomen. Discoloration may then, however, gradually extend to the entire body surface. The spread of bacteria within the veins in subcutaneous fatty tissue and hemolysis of red blood cells

Figure 4 Temperature-time of death nomogram for ambient temperatures up to 23 °C. At the scene of crime, for instance, a rectal temperature of 27 °C at an ambient temperature of 15 °C were measured. At first, the point of the scale of the measured rectal temperature and ambient temperature have to be joined by a straight line (yellow) which crosses the diagonal of the nomogram at a specific point. For the second step, a second straight line has to be drawn passing through the center of the circle (lower left of the nomogram) and the intersection of the first line and the diagonal (red line). The second line crosses the semicircles for different body weights. The time since death (in this case, for 70 kg bodyweight) can be read off at the intersection of the semicircle of the given body weight. The intersection gives the mean time since death, and the intersection with the outer circle, the 95% limits of confidence, which may be higher if corrective factors have to be used.

Table 3 Empiric corrective factors (c.f.) for body weights. The listed values of c.f. apply to bodies of average weight (reference: 70 kg, see Table 10) in an extended position on a thermally indifferent supporting base

Dry clothing/covering	Air	Corrective factor	Wet through clothing/Covering wet body surface	In air	In water
		0.35	Naked		Flowing
		0.5	Naked		Still
		0.7	Naked	Moving	
		0.7	1–2 thin layers	Moving	
Naked	Moving	0.75			
1–2 thin layers	Moving	0.9	2 or more thicker layers	Moving	
Naked	Still	1.0			
1–2 thin layers	Still	1.1	2 thicker layers	Still	
2–3 thin layers		1.2	More than 2 thicker layers	Still	
1–2 thicker layers	Moving or still	1.2			
3–4 thin layers		1.3			
More thin/thicker layers	Without influence	1.4			
		–			
Thick blanket		1.8			
		–			
+		2.4			
		–			
Clothing combined		2.8			

'Thermally indifferent' supporting bases are, for example, usual floors of rooms, dry soil, lawn, asphalt. In comparison, bases which appear more thermally insulating heat than conducting should additionally be taken into account. (a) Excessively thickly upholstered bases require c.f. of 1.3 for naked bodies. In cases of clothed bodies, c.f. should be increased by 0.1 units (thickly clothed) to 0.3 units (very thickly clothed). (b) Insulating but not excessively thickly upholstered bases such as a mattress (bed) or thick carpet require c.f. of 1.1–1.2 for naked bodies. (c) Bases that accelerate cooling, for example, concrete, stony, or tiled bases on ground, require c.f. up to 0.75 for naked bodies. (d) In cases of clothed bodies lying on bases, c.f. should be reduced by 0.1 units (thicker clothes) or by 0.2 units (very thin clothes).

Table 4 Intrinsic and extrinsic factors influencing onset and extent of postmortem changes (according to Tsokos, 2005)

<i>Acceleration of onset and extent of postmortem changes</i>
Death occurring in a hot, moist environment/under high ambient temperatures
Body surface insulation by warm clothing or other covering
Considerable time interval elapsed after death until artifactual cooling of the body was started
Subject was overweight/had a high fat content
Subject suffered/died from underlying infection or sepsis
Subject was intoxicated (e.g., with illicit drugs such as heroin)
Subject suffered/died from open wounds (perforating/penetrating traumatic injuries such as stab wounds, gunshot wounds, impalement injuries) or during surgical procedures
<i>Deceleration of onset and extent of postmortem changes^a</i>
Death occurred in a cold, dry environment/under low ambient temperatures
Subject was scantily dressed/naked/undressed shortly after death
Subject was stored in a cooling device shortly after death

^aThese factors decelerate the rate of postmortem changes but do not in general alter the underlying postmortem biological processes.

causes the venous 'marbling' of the skin (Figure 5). A further feature of putrefaction is the formation of putrefaction transudates (accumulations of putrefied fluids) leaking out of the dermis and causing the epidermis to detach from the dermis. Such putrefactive blisters may grow to large sizes, finally even tearing apart the epidermis, causing it to come off in shreds and exposing the dermis, which can very quickly dry out and change to brown. In addition, during putrefaction, hair and nails loosen and can then easily be pulled out. This looseness of finger and toenails and hair found in drowned bodies is an

important criterion for determining the length of time of their deposition in water. In the course of putrefaction, there is finally liquefaction of fatty tissues. Liquid fat may then leak out of the body like butter or margarine when there are skin defects, and there might be decomposition of the body's proteins (proteolysis), during which there is accumulation of biogenic amines (putrescine, cadaverine, histamine, choline, etc.) as well as cadaveric alkaloids, referred to as ptomaines (cadaveric poisoning). Even though these ptomaines have shown muscarinic atropine-like effects in tests on animals, we cannot use the term ptomaine/cadaveric poisoning to indicate that it makes the area around a putrescent corpse 'toxic.' Health risks from corpses, similar to those from living people, originate from infectious pathogens (tuberculosis, hepatitis, human immunodeficiency virus (HIV)), as these pathogens are able to survive the death of their host (the deceased person) (Table 5).

During bacterial proteolysis, certain amino acids such as delta-aminovaleric acid or gamma-aminobutyric acid can be found in brain and liver, which can be used to make a rough estimate of the time elapsed since death. Further symptoms arising from gas accumulation and gas bloating are the formation of so-called foam organs – organs permeated with gas and macroscopically detectable cavities – as well as the leaking of putrefactive fluids from mouth, nose, anus, and genitalia. In pregnant women, the pressure arising from putrefactive gas may cause the fetus to be expelled through the genitalia, a phenomenon described by the macabre term 'coffin birth.' While early signs of decomposition can be used for a rough estimate of the time of death, the sequence of symptoms of decay depending on previous organ disease, duration of agony, environmental conditions, especially the ambient temperature, bacterial infestation, and other factors are so variable

that one cannot draw conclusions regarding the time of death (Table 6), but make very gross estimates only. A rule of thumb going back to the Berlin forensic physician Johann Ludwig Casper (1796–1864) – named Casper’s Law, after him – says that 1 week in air equals 2 weeks in water equals 8 weeks buried in the ground. Casper’s Law thus highlights the decomposition process under different environmental conditions (air, water, earth) but does not allow precise determination of time of death.

Figure 5 Venous marbling over an arm.

Table 5 Morphological changes in the putrefaction phase. Aboveground exposure at 20–24 °C (68–75 °F) without insect infestation. According to Berg

Indication	Interval after death
Initial greenish discoloration of the abdominal skin	1–2 days
Cutaneous venous marbling	2–4 days
Beginning of film-like slippage of the epidermis	5–6 days
Loss of pigmentation in the <i>stratum germinativum</i>	6–8 days
Putrefactive blisters and putrefactive transudates in the body cavities	8–14 days
Putrefactive emphysema in the <i>subcutis</i>	8–14 days
Bloating of abdominal cavities	8–14 days
Diffusion of all fluids, collapse of organs	Usually not until months later
Beginning of mummifying	Usually not until months later
Dehydration of soft tissues	Usually not until months later

Please note that this table gives only rough indications for the sequence of putrefaction in cadavers exposed aboveground at a relatively narrow range of temperature. Numerous deviations are possible, depending on the body’s built, the underlying surface, coverings, and terminal illness.

Table 6 Criteria used in estimating the age of inhumed bones, average indications for neutral to alkaline, calcareous soil subject to weather conditions

Indication	Interval in years						
	0–5	5–10	10–20	30–50	50–100	100–1000	>1000
Odor activity	+	–	–	–	–	–	–
Impregnation of fat at the epiphyses	+	+	–	–	–	–	–
Remnants of soft tissue	+	+	(+)	–	–	–	–
Adipocere efflorescence on the surface	+	+	+	–	–	–	–
Filling of the medullary cavity	+	+	+	(+)	–	–	–
Presence of adipocere, histological	+	+	+	+	(+)	+	+
Presence of collagen, histological	+	+	+	+	+	+	(+)
UV fluorescence	+	+	+	+	+	+	(+)
Hardness, heaviness	+	+	+	+	+	+	(+)

Preservation of Decomposing Bodies

Regarding the skin, the essential signs of putrefaction are hemolysis, transudation, and accumulation of gas. It is possible to prevent signs of putrefaction for a longer period of time by special storage conditions, for which it is of utmost importance that packaging of the body or body parts is extremely airtight.

Experimental investigation of the influence of vinyl materials on postmortem alterations in rabbit and mice cadavers kept in plastic bags of different air volumes (3 l/five pints, one liter/13/4 pints, no air) at room temperature revealed a clearly delayed decomposition by storage in plastic materials. The volume of air in the bag is obviously of great importance for the progression of decay. In one particular case of a body which had been dismembered to hide evidence with the parts wrapped in plastic bags, an extremely good state of preservation after a period of 2 years allowed even positive dactyloscopic identification, despite epidermolysis (Figure 6). Along with the inhumation of the body parts in winter time, one factor for preservation in this case was considered to be the very airtight packing into plastic bags, together with physical covering clearly contributing to delayed decomposition processes.

Destruction of Corpses by Maggots

Maggots may contribute significantly to the destruction of a corpse (Figure 7). Flies may begin to lay eggs on a body even in the period preceding death. Depending on the ambient conditions, egg deposits can often be seen in the nostrils and in the angles of mouth and eyes. Egg deposits develop into maggots, then pupae, followed by empty pupal shells and adult flies. The development cycle lasts between 3 and 5 weeks, depending on species and temperatures. Maggots produce enzymes which can break down proteins and feed on disintegrated soft tissues. In summer, it is possible for maggots to reduce an above-ground cadaver nearly completely to a skeleton within a few weeks time. For the coroner, an additional problem is that eggs are frequently deposited in wounds to the skin while the subject is still alive, resulting in extensive destruction to the wounds with loss of evidence regarding the cause of death.

Figure 6 Body parts found in garbage bags.

Figure 8 Mold colonizing over a cadaver.

Figure 7 Development cycle of the fly: egg mass, maggots, pupae, and adult flies (Original Dr. Marco Strehler, Institute of Forensic Medicine, University of Bonn).

Decomposition

Decomposition, as distinct from putrefaction, is a dry, acidic process on an oxidative basis, leading to the splitting off of acids (H_2CO_3 , H_3PO_4 , and H_2SO_4). Decomposition is accompanied by a rancid odor described as a musty or rotting smell. Very often colonies of mold can be found (Figure 8).

The Chemistry of Decomposition

While putrefaction is mainly an anaerobic bacterial reduction process, decomposition is dominated by aerobic microbiological processes, which may create pungent, rotten odors originating from the metabolic products of oxidation.

Period up to Skeletonization

The period up to skeletonization varies widely, depending on the storage conditions of the body; this has already been expressed by Casper's Law, saying that a corpse on the ground decomposes more quickly than one in water or underground,

although the ratios Casper has defined are certainly also subject to numerous variations. Bodies lying on the surface of the ground are as a rule skeletonized within 1 year, and after 2 years the bones are almost completely free from soft tissues. Considerable proportions of soft part reduction during summer result from maggot infestation and animal predation. Such conditions may make a body completely skeletonized within a few weeks (Figure 9). If a body is stored underground, the time required for skeletonization depends essentially on the composition of the surrounding soil. Under normal conditions, with usually water-permeable, aerated soil at a depth between 1 and 2 m (3 ft 3 in. to 6 ft 6 in.), about 5–7 years are needed for complete skeletonization, although considerably longer periods have been recorded. In warmer climate, skeletonization normally happens in clearly shorter periods. Results of exhumations indicate, however, that even after burial times of 5–7 years, some bodies plus clothing were often found well preserved. In some cases, even the inner organs with the gastrointestinal tract were still intact. This is of particular importance as, among other issues, toxic substances and their routes of ingestion have to be determined. Bodies interred in crypts or sarcophagi may undergo mummification (see later). A form of interment particularly in warmer countries is the mausoleum, usually a marble-clad building with up to five aboveground rows of sealed cells. Depending on ventilation and time of interment (summer or winter), mummification or putrefaction, larval infestation and gangrenous decay occur. The rate of decomposition is considered between that of aboveground exposure and burial in soil. Finally, special conditions apply to burials in mass graves. Even if bodies are buried together simultaneously, they may display quite different degrees of decomposition. Bodies lying at the periphery are usually extensively decomposed, while bodies at the center may still have good preservation of soft tissues (see later) with pronounced grave wax formation (see later). The bones of bodies lying aboveground are, as a rule, completely skeletonized after 1–2 years, showing no remnants of soft tissues, and no traces of cartilage or tendons. In inhumed bodies, remnants of soft tissues may still be found up to the second decade after burial, but more rarely after the third or fourth decade. Remains of clothing can be preserved for longer. With ongoing time, the originally smooth surfaces of

Figure 9 A cadaver partially skeletonized by maggot infestation. Postmortem interval of about 2 weeks in an apartment in summer.

buried bones show signs of wear. Deterioration of the bone surfaces strongly depends on the composition of the surrounding soil (**Figure 10(a)**). Bones may lie intact in graves and crypts for centuries, and several criteria allow for rough estimates of their ages (**Table 6**). Therefore, the medullary cavities of relatively recently living bones still show adipocere, whereas centuries-old bones are free of adipocere (**Figure 10(b)**). Even after soft tissues, particularly muscles and inner organs, have largely been consumed during the advanced stages of putrefaction and decomposition, there are often portions of more decay-resistant skin still present covering the bones.

Animal Predation

Even in the early postmortem interval, there may already be traces of animal predation, not only from rats or mice, or – in water – crabs and fish, but also from pets (dogs and cats). Mice will typically gnaw away the epidermis, leaving characteristic gnaw marks (**Figure 11**).

Extensive damage by a dog to soft tissues immediately after death can be explained by the dog's wish to obtain a reaction from its lifeless owner, first licking the face, and then, without result, behaving instinctively, biting, and mutilating.

Preservation Processes in Cadavers

While natural processes described so far (autolysis, putrefaction, and decomposition) cause dissolution and disintegration of the cadaver down to bones and tendons, special environmental conditions may preserve the body. Preservation processes include mummification and adipocere formation, which are also found in bog and permafrost corpses.

Figure 11 Characteristic mice gnaw markings on the epidermis of the left hand.

Mummification

Mummification usually takes place when the water in the body's tissues evaporates due to dryness and good ventilation. Mummification from natural processes may occur in bodies

buried in churches or crypts (e.g., the lead cellar of Bremen cathedral), but it can also be seen in bodies lain at home or indoors for some time. Mummification dries the skin into a hard leathery state, dehydration sometimes causing the body to be fixed in the position it had assumed at the time of death. Furthermore, there is substantial weight loss, due to desiccation and shrinking of tissues. Rapid loss of water contributes to mummification, caused by storage in dry drafty air on a warm and dry ground. Mummification leading to leathery, hard stiffening of the skin may, under appropriate environmental conditions, begin relatively quickly (already after 2–3 days), starting at the limbs (fingers, toes, tips of the nose and chin, ears, skin over the cheekbones). Pronounced mummification, however, as a rule, is not detectable until after several weeks.

Decomposition of the Body in the Grave – Saponification

A body buried in soil should be reduced to a skeleton after 15–20 years, at the most. It is well recognized that skeletons may remain preserved much longer (e.g., several centuries). Whether a corpse largely decomposes within this period, however, also depends mainly on properties of the soil – mineral composition and aeration – and on groundwater conditions.

Grounds where the coffins actually lie in groundwater are unsuitable for burials, or where the area of decay constantly or temporarily contains groundwater, or even areas subject to flooding used for the production of water for public use. Nevertheless, under such conditions, preservation processes such as saponification – formation of adipocere or grave

Figure 12 (a) Soft tissues of the thighs were converted into hard shells of adipocere, with the long bones hanging loosely. (b) Saponification of the head. (c) The leg of a newborn child, with saponification, after lying in flowing water for several months. The outer shape of the leg was preserved; the chalk-like brittle mass, which looks like a stiff tube, contains loose bones. The muscles are missing. (d) The texture of the fat nodules in the subcutaneous fatty tissue was fixed by adipocere formation (*état mammellonné*).

wax – may occur. Saponification can be observed in bodies having lain in a completely or partially hermetic damp environment (e.g., water corpses and damp graves). During formation of adipocere, unsaturated fats (oleic acids) are converted into saturated fats (palmitic and stearic acids). Saponification begins in the skin after about 6 weeks and in muscles after 3–4 months. Entire extremities may be converted into adipocere, although this requires several months to years (Figure 12(a)–12(d)). The term adipocere (adepts = fat, cera = wax) goes back to Fourcroy (1789) and Thouret (1792) who, during the closure of a cemetery in Paris, noticed that the bodies buried there, some in groups, had not ‘wasted away,’ but had been preserved in the same characteristic way.

Permafrost Bodies

Extensive body preservation may also occur in permanently frozen ground. Permafrost bodies were found in northern Canada, for example, in the early 1980s. The bodies were of members of the Franklin expedition in the 1840s. The cadaver found in the Hauslabjoch area of the Italian Alps (‘Ötzi’) is a famous frozen body from central Europe.

Bog Bodies

In bog bodies, the effects of humic acid include bone demineralization, tanning of soft tissues, and typical reddening of the hair. Due to preservation of the body surfaces, it is possible to collect significant evidence on circumstances and cause of death. Along with the presence of tannin and humic acid, a third factor is the oxygen-poor peaty soil suppressing putrefaction processes, which thus contributes to good preservation. Along with tanning of skin and hair, some of the internal organs remain preserved, but muscle and fatty tissue usually disintegrate. The high acid content of the soil softens bones. Bog bodies are of special value, not only archeologically, but also forensically, as evidence of injury relating to the cause of death has been saved by preservation of the body.

Livor mortis, rigor mortis, algor mortis, other factors.

Estimation of the Time Since Death

B Madea, University of Bonn, Bonn, Germany

© 2013 Elsevier Ltd. All rights reserved.

Introduction

Estimation of the time since death is a practical task in daily forensic casework. The main objective is to give the police a first estimation on the time since death already at the place where the body was found. Methods of estimating the time since death should be of course as precise as possible but even more important is reliability. The main principle of determining the time since death is the calculation of a measurable date along a time-dependent curve back to the start point. Characteristics of the curve (e.g., the slope) and the starting point are influenced by internal and external and antemortem and postmortem conditions. Therefore, the estimation of the time since death will never reveal a time point but an interval.

Methods of estimating the time since death are based on two different approaches:

- Which antemortem changes, either physiological or pathological, can be detected and allow, together with police investigations, a conclusion on the time since death (survival time)?

Methods like wound age estimation and gastric emptying when time and volume of the last meal are known follow this approach.

- Which postmortem changes allow a conclusion to be made on the time since death?

Most methods which are used in practice follow this second approach.

There is a huge literature on methods proposed for estimating the time since death. However, most have never gained practical importance.

The methods proposed for estimating the time since death are completely different in nature:

- Predominantly physical processes like body cooling and hypostasis
- Metabolic processes, for example, concentration changes of metabolites, substrates, activity of enzymes
- Autolysis (loss of selective membrane permeability, diffusion according to Fick's law with increase or decrease of analytes in various body fluids, morphological changes)
- Physicochemical processes (supravital reactivity, rigor mortis, immunological reactivity)
- Bacterial processes (putrefaction)

Furthermore, the methods for estimating the time since death are not only different in nature, but have a widely differing scientific value concerning the underlying scientific background, the mode of investigation, and the validation of the method.

The highest scientific value is of course attributed to methods with a quantitative measurement of the postmortem changes, with a mathematical description which takes into account influencing factors quantitatively. Clear data on the precision of the method are available and these data have been proved on independent material and in field studies.

On the other hand, the lowest scientific evidence for death time estimation is acquired by methods that provide just a subjective description of the postmortem change. The progression of postmortem change is entirely dependent on ambient factors. However, these ambient factors cannot be taken into account quantitatively.

For estimating the postmortem interval (PMI) during criminal investigations, different sources are used (Pounder):

- (1) Evidence on the body of the deceased (postmortem changes)
- (2) Information from the environment in the vicinity of the body (date of the newspaper, open TV program)
- (3) Anamnestic factors concerning the deceased's habits (leaving the apartment, arriving at work, day-to-day activity)

For the forensic investigation of the time since death, all sources of information on the time since death should always be used, though the focus of the forensic pathologist is of course the postmortem changes.

Temperature of Corpses

From all methods of death time estimation, postmortem body cooling has been studied most extensively and some of the investigations in the following list fulfill the criteria for high-quality research:

Quantitative measurement, mathematical description, taking into account influencing factors quantitatively, declaration of precision, and proof of precision on independent material.

The cooling of bodies is mainly a physical process and the factors affecting the rate at which a body cools after death were identified long ago.

For estimation of the time since death only central core temperatures like rectal temperature or brain temperature should be taken as a surface can cool down already during life (Figure 1). The Glasgow professor, Henry Rainy, was one of the first to realize that Newton's law of cooling does not describe the decrease of rectal temperature due to the postmortem temperature plateau. Rainy transferred Newton's rule of cooling to the cooling of bodies and, thus, he considered the environmental temperature. By measuring the temperature several times, he could even determine experimentally the individual steepness of temperature decrease. Furthermore, he had already identified the postmortem temperature plateau as the declination of the single-exponential model and he consequently identified the estimated time since death using Newton's law as minimum time. By multiplication with 1.5, he revealed also a maximum time.

It was not before the two-exponential model of Marshall and Hoare in 1962 that a real breakthrough could be noticed: The exponential term with exponent p stands for the postmortem temperature plateau and that with exponent Z for the Newton-part of cooling after the plateau:

Figure 1 Cooling curve from different body sites.

$$\frac{T - T_u}{T_o - T_u} = e^{-Zt} - e^{-pt} = \frac{P}{p - Z} e^{-Zt} - \frac{Z}{Z - p} e^{-pt}$$

where T is the deep rectal temperature ($^{\circ}\text{C}$); T_o is the rectal temperature at death, fixed at 37.2°C ; T_u is the ambient temperature ($^{\circ}\text{C}$); t is the time of death (h); $Z = 0.059 - 0.00059$ (0.8 AM^{-1}) with A , body surface according to DuBois and M , body weight; $P = -0.4$.

In 1974, Brown and Marshall demonstrated that more than two-exponential terms complicated the model without leading to more precise results. With this model, Marshall could individually determine time of death by a single measurement of the rectal temperature considering body proportions and (constant) ambient temperature under standardized conditions of cooling (unclothed, not covered, standing air, stretched supine position). Surprisingly, this breakthrough in death time determination did not meet with great response. The new model was only described in a general application report and included in one textbook.

Rectal Temperature Time of Death Nomogram

A further breakthrough was achieved with the investigations by Henssge who presented a simplified method to determine the Newton cooling coefficient. He determined statistical figures for the deviation between calculated and real death times for cooling under standardized conditions. These data on the precision were at first valid for standard conditions of body cooling:

- naked body with dry surfaces
- lying extended on the back
- on a thermally indifferent base

- in still air
- in surroundings without any source of strong heat radiation
- in constant ambient temperature

Furthermore, Henssge extended the application spectrum of the double-exponential formula to different cooling conditions by using empirical body weight correction factors and published nomograms for reading the time since death instead of calculating it.

From all methods of estimating the time since death, the nomogram method by Henssge based on body cooling after death is the most intensively investigated, most precise, and reliable procedure. For the application of the nomogram method in case work, the following points have to be taken into consideration:

Inspection of the body posture, clothing, covering, sunshine on the body, windows (closes, opened: when?), radiators, floor (thermally indifferent?) on the scene of crime.

Measurement of ambient temperature (air) close to the body and at the same level (10–20 cm above the base); measurement of the temperature of the underlying surface as well. Have any changes of thermic conditions been made since the body was found?

Single measurement of deep rectal temperature at the scene using an officially calibrated electronic thermometer with probes for measuring air, surface, and rectal temperature. The deep rectal temperature must at least be measured 8 cm within the anal sphincter.

Estimation of the body weight. At autopsy control to check whether the estimation was correct.

Evaluation of the corrective factor. Are there any conditions which accelerate or delay cooling compared to standard conditions? For rectal temperature, thermic conditions of the lower trunk only are relevant:

- clothing/covering
- resting or moving air
- kind of supporting base
- In cases of strong insulation conditions and very high or low body weight, the corrective factor must be adapted to the body weight
- Use of the nomogram

Requirements for use:

- no strong radiation (e.g., sun, heater, cooling system)
- no strong fever or general hypothermia
- place of death must be the scene where the body was found
- no uncertain severe changes of the cooling conditions in the period between death and examination
- no high thermal conductivity of the surface beneath the body
- longer agonal period after fatal injury (time since death may be inconsistent with the time of assault)

Connect the points on the scales for rectal and ambient temperature by a straight line. This line crosses the diagonal at a particular point. Draw a second straight line going through the center of the circle below left of the nomogram and the intersection of the first line and the diagonal. The second line crosses the semicircles which represent the body weight. At the intersection of the semicircle with the body weight, the

time of death can be read. The second line touches a segment of the outmost semicircle. Here the permissible variation of 95% can be seen for standard cases or cases using corrective factors.

The nomogram was at first constructed for chosen standard conditions of cooling (naked body with dry surfaces, lying extended on a thermally indifferent base in still air). Conditions with improved or delayed body cooling compared to standard conditions reduce or increase the real body weight. Extensive cooling experiments under varying cooling conditions led to empirically found corrective factors for body weight (Table 1). With these corrective factors, the nomogram can be used for nonstandard cases as well. Systematic examination revealed that higher correction factors (e.g., for clothes and/or blankets) have to be used for lower body weights. That means that corrective factors themselves are dependent on the body weight. Higher body weights need lower factors and, vice versa, lower weights need higher factors. Furthermore, the nomogram can also be used in cases of sudden change of ambient temperature and in cases with ranges of the ambient temperature and the corrective factor. This nomogram was developed for ambient temperatures below 23 °C. For ambient temperatures above 23 °C, another nomogram was developed based on the published material of De Saram et al.

Brain Temperature Time of Death Nomogram(s1)

The two-exponential model by Marshall and Hoare was also suitable for the mathematical description of the brain temperature drop curve:

$$\frac{T_{\text{Brain}} - T_U}{37.2 - T_U} = 1.135e^{-0.127t} - 0.135e^{-1.07t}$$

According to the rectal temperature time of death nomogram, a brain temperature time of death nomogram was constructed. Up to 6.5 h postmortem, the most precise computation of time

of death was achieved by the exclusive application of brain temperature, which gave a time of death within ± 1.5 h (95% confidence limits). Between 6.5 and 10.5 h postmortem, the brain/rectum-combined computation of time of death balanced in the ratio of 6–4 was the most precise one, at ± 2.4 h. Beyond 10.5 h postmortem, the most precise computation of time of death was achieved by exclusive application of rectal temperature, which gave a time of death within ± 3.2 h.

Field Studies

Meanwhile, both a single center and a multicenter study on the accuracy of the nomogram method compared to the investigations of the police were carried out. Both studies covered a wide range of ambient temperatures, body weights, and corrective factors. The estimated period did not contradict the investigated period in any of the cases. Especially in the early stages, police investigations can be greatly supported by this method.

Cooling Dummy

More than 20 years ago, a cooling dummy which reproduces almost exactly the cooling of corpses was developed. With this dummy, cooling can be simulated in any condition, for example, even at the location where the body was found. The cooling dummy is an essential help in cases when body cooling under rare cooling conditions has to be evaluated.

Compound Method

From all methods of death time estimation, the nomogram method is the most intensively investigated, most precise, and reliable procedure. However, in the best case, a precision of ± 2.8 h around the mean value (95% confidence limits)

Table 1 Empiric corrective factors for body weight

Dry clothing/covering	Air	Corrective factor	Wet through clothing/covering wet body surface	In air	In water
		0.35	Naked		Flowing
		0.5	Naked		Still
		0.7	Naked	Moving	
		0.7	1–2 thin layers	Moving	
Naked	Moving	0.75			
1–2 Thin layers	Moving	0.9	Two or more thicker layers	Moving

Clothing combined		2.4			
		2.8			

can be achieved. Therefore, other methods of death time estimation should be used to narrow down this range further (electrical and mechanical excitability of skeletal muscles; chemical excitability of the iris; lividity and rigor mortis) (Table 2). But how to use the different data on various time-dependent postmortem changes?

Mean values do not represent the time frame in which a special degree of postmortem changes may be positive. For instance, the mean value of degree IV of electrical excitability of the orbicularis oculi muscle is 5.5 h; however, it may be positive between 3 and 8 h. Therefore, not the mean values but the upper and lower range should be used for death time estimation. For case work, the data of the described times of death and supravital reactions were, together with the signs of death estimation, based on the nomogram rearranged into a special chart which facilitates the choice of the subsequent helpful criteria in an actual case (Figure 2). In casework, the examination begins with taking rectal and ambient temperatures and choosing the appropriate corrective factor and a first estimation of the time since death using the nomogram. Concerning temperature measurements and choosing the appropriate corrective factor, see the chapter on early and late postmortem changes. Then the further criteria are examined. Especially those criteria are of interest which can narrow down the time frame by the nomogram method further. Using

this chart at the scene of crime or a computer program, it is guaranteed that nothing will be forgotten and the inspection and examination of the body is efficient and complete concerning death time estimation. For instance, at the scene of crime, the nomogram method reveals a death time between 4.5 h (lower limit) and 10.5 h (upper limit) (Figure 3). The lower limit can be confirmed or improved only by a criterion with a higher value than 4.5 h, and the upper limit can be reduced only by a criterion with a lower value than 10.1 h. The electrical excitability of facial muscles (musculus orbicularis oculi) showed a positive reaction according to degree IV; that means time since death was below 8 h. Therefore, the upper limit of death time estimation (10.1 h) could be reduced to 8 h. In the early postmortem period especially, the combined application of the nomogram method and electrical excitability of facial muscles increases the precision of death time estimation from body cooling alone. Even if the result of the nomogram method is not improved but just confirmed, this confirms also the self-confidence of the investigator in his opinion and statement of the time since death as his estimation is based on two independent criteria. If the nomogram method must not be used, for example, in cases of hypothermia or fire in the setting where the body was found, the other methods may give reliable results on the death time estimation.

Table 2 Table for estimation of the time since death based on supravital reactions and postmortem changes

Time after death (hpm)		
<i>Electrical excitability</i>		
Musculus orbicularis oculi	VI Upper and lower eyelid + forehead + cheek	1–6
	V Upper and lower eyelid + forehead	2–7
	IV Upper and lower eyelid	3–8
	III Whole upper eyelid	3.5–13
	II 1/3 to 2/3 of the upper eyelid	5–16
	I upper eyelid local around the puncture electrodes	5–22
Musculus orbicularis oris		3–11
Thenar muscle		Up to 12
Hypo thenar muscle		Up to 12
<i>Pharmacological excitability of the iris</i>		
Mydriatica	Noradrenalin/adrenalin	14–46
	Tropicamid	5–30
	Atropine/cyclopent	3–10
	Acetylcholine	14–46
Miotica		
Drop of body core temperature (rectal temperature)	At first temperature plateau of 2–3 h, thereafter appr. 0.5–1.5 °C h ⁻¹ , depending on ambient temperature, clothing, covering, body proportions, weather conditions (wind, rain)	
Drying of the cornea (open eyes)	After 45 min	
Drying of the cornea (closed eyes)	After 24 min	
<i>Postmortem lividity</i>		
Beginning	After 15–20 min	
Confluence	~1–2 h	
Maximum	After a few hours (~6–8)	
Complete displacement on thumb pressure	~10 h (10–20 hpm)	
Displacement after turning the body	~10 h	
Rigor mortis (jaw)	After 2–4 h	
Complete rigidity	After 6–8 h	
Beginning of resolution	After 2–3 days depending on the ambient temperature	
Reestablishment possible	Up to 8–12 hpm	
Complete resolution	After 3–4 days, in deep ambient temperatures, rigor mortis may be preserved much longer

Figure 2 Integrating chart for casework at a scene of crime.

A recent field study on the compound method on 72 consecutive cases over a longlasting PMI revealed that in 49 cases the limits of the period since death by the temperature methods were improved by the non-temperature methods. The degree of electrical excitability was the most valuable additional method, but the classical signs of death may improve the nomogram results as well.

Further Methods

Vitreous Potassium

There is huge literature especially on chemical methods of death time estimation. Among these are many in vitro methods. Most chemical methods of death time estimation have a factor in common that they are of no value in practice.

TIME OF DEATH	between 02.00 and	05.30

Figure 3 Integrating chart for casework at a scene of crime with an example.

While the earlier studies were mainly carried out on blood and cerebrospinal fluid (CSF), for more than 60 years, most investigations have been performed on vitreous humor (VH). This is mainly due to the fact that VH is topographically isolated and well protected and, thus, autolytic changes proceed slower compared to blood and CSF. The most studied parameter in VH is potassium. Postmortem rise of the potassium concentration (K^+)

in VH has been known for 50 years and has been recommended for the estimation of the time since death. However, the practical application has been hampered by different results concerning the accuracy of death time estimation. Optimistic results of early investigations with an accuracy of death time estimation of ± 9.4 h in a time period up to 104 h postmortem could not have been confirmed by succeeding investigations.

The correlation and the strength of correlation between K^+ and the time since death depend on different factors such as cause of death, duration of agonal period, ambient temperature, etc. These factors influencing the accuracy of death time estimation can partly be taken into consideration by using internal standards (urea concentration as an indicator of an antemortem electrolyte dysregulation). For example, in cases with electrolyte dysregulation due to impaired renal function, the precision of death time estimation by vitreous potassium is lower than in cases with normal renal function. However, even in the most favorable case, precision of death time estimation is ± 22 h up to 5–6 days postmortem.

In most investigations on vitreous potassium, the PMI has been used as the independent and K^+ as the dependent variable in linear regression analysis between PMI and K^+ . According to a recommendation of Munoz et al., however, K^+ should be used as the independent variable for regression analysis. According to the authors, this approach leads to a higher accuracy of death time estimation. This could be confirmed by own calculations.

Another statistical approach has reevaluated six large studies on the rise of vitreous K^+ using a local regression analysis (Loess procedure). Based on this reevaluation, an accuracy of death time estimation has been recommended (95% limits of confidence of ± 1 h in the early PMI and ± 10 h 110 h postmortem) which has surpassed even optimistic results of earlier investigations. This recommended accuracy of death time estimation has been checked on an own random sample of 492 cases. Only 153 cases have been within the predicted PMI, while 339 lay outside with a systematic overestimation of the time since death. Furthermore, the accuracy of death time estimation cannot be confirmed. As the precision of death time estimation by vitreous potassium is low, the author knows of no case worldwide where this method has been used as evidence for the PMI. The amount of literature on vitreous potassium is reciprocal to its practical importance.

Gastric Contents and Time Since Death

Although examination of gastric contents is mentioned as a method to determine the time since death nearly in every textbook, gastric content alone allows only a rough estimation of the interval between the last meal and death. Time and size of the last meal have to be known to derive conclusions on the survival time between last food intake and death. State of digestion and the distribution of the last meal in the stomach and upper intestine have far long been proposed as a method to estimate the time since death. Even if the volume of the last meal is not known, the type of the meal (breakfast, lunch, dinner) may allow rough estimation of the daytime when death occurred. Gastric emptying has been studied and quantified in the last decades using different methods (radiologic, intubation, aspiration, radio isotopes, ultrasound, absorption kinetics of orally administered solutes, pheromagnetic traces). Liquids leave the stomach much faster than solids. While gastric emptying obviously follows an exponential function for liquids, solids show a linear emptying pattern. The following gastric emptying times are given in the literature: 1–3 h for a light small-volume meal; 3–5 h for a medium-sized meal; 5–8 h for a large meal. However, it must be kept in mind that

different anatomical and functional disorders cause delayed or rapid gastric emptying. According to a review by Horowitz and Pounder, only solid components of a mixed solid and liquid meal should be considered and the weight of the stomach content should be compared with an estimated weight of the last meal and reference made to the known 50% emptying times for the solid components of meals of various sizes.

Putrefaction

Putrefaction is a bacterial process, predominantly influenced by environmental factors, mainly ambient temperature, but by underlying diseases and body proportions as well. Medical treatment with antibiotics in the terminal phase may delay putrefactive changes. Otherwise, in cases of sepsis, advanced putrefaction may be seen soon after death. Advanced stages of putrefaction may be seen within a few hours after death which, in moderate or cold climate, are not seen after weeks. Even in relatively constant ambient temperatures, the progression of putrefaction varies considerably (Table 3). Therefore, putrefactive changes are not a sound method for estimation of the PMI.

Recently, there seems to have been a change, since methods developed in radiology like H magnetic resonance spectroscopy (MRS) have been applied for the identification of metabolites emerging during decomposition of brain tissue as a step toward quantitative determination of PMIs in putrefaction.

Brain decomposition resulted in reproducible concentration changes of known metabolites and the appearance of decay products that had to be characterized first.

The investigations on postmortem decompositions by H MRS may represent a real progress in research for the following reasons:

- A noninvasive chemical analysis in situ is possible with quantitation of analytes.
- Longitudinal studies of postmortem changes with reproducible results are possible.
- The sheep model seems to be valid for human brains as well.

Table 3 Progression of putrefaction of bodies in air, temperature of about 20 °C

<i>Progression of putrefaction of bodies in air, temperature of about 20 °C</i>	
After 1–2 days	Green discoloration of abdominal wall, softening of eyeballs
After 3–5 days	Dark green discoloration of great parts of the abdominal wall. Some patchy green discolorations of the skin of other body regions. Bloody fluid leaking out from mouth and nostrils. Marbling
After 8–12 days	Whole body surface dark green. Face, neck, and thoracic wall partly reddish green. Bloating of abdomen, scrotum, and face. Fingernails still fixed. Hair loose, begins to peel
After 4–20 days	Whole body green or reddish brown. Bloating of the whole body. Blisters, partly filled with putrefactive fluid, partly burst with desiccation of the dermis. Eyes (iris, pupil, sclera) reddish brown discolored. Fingernails peeling

- With this model, influencing factors like temperature can be easily studied.
- The definition of analytical functions for the time courses of ten metabolites up to 400 h postmortem was successful.
- Prediction of PMI based on the combination of five metabolites correlates very well with true time postmortem up to 250 h postmortem.
- These metabolic changes cover a PMI where no other method allows a quantitative calculation of the time since death with any acceptable degree of certainty.

Putrefaction in Water

For bodies recovered from water, quite a good and reliable method for estimating the minimum and maximum water time has been developed based on putrefactive changes which are visible at external examination or at the dissection of the body.

This is mainly due to the fact that water temperature is relatively constant over a longer period of time and during day and night, while air temperature differs not only from day to night but from one day to the other. Morphological findings which are taken into consideration for the estimation of duration of immersion in immersed bodies are listed below:

External findings

1. Rigor mortis
2. Lividity
3. Marbling
4. Bloating of face, scrotum, subcutaneous tissue
5. Discoloration of skin (green, black, reddish)
6. Loss of epidermis
7. Loss of hairs
8. Hands
 - (a) washerwomen's skin
 - (b) loosening of nails
 - (c) peeling of skin

Table 4 Chart to estimate the minimal time interval of immersion

	Month	Jan	Feb	Mar	April	May	June	July	Aug	Sept	Oct	Nov	Dec

8.	Peeling of skin in glove form	35	(45)	23	16	10	3	3	3–4	4	7	20	28
9.	Nails lost	Over 53	45	30 (40)	21	14	8	3	4	10	Over 11	20	Over 35
10.	Feet: beginning of wrinkling	(1)	(1)	(12 h)	(1)		(6 h)	0.5 h		2 h		2 h	(1)
11.	Nails become loose	Over 53	40	26 (35)	17	10	5	3	4	8	12	17	28
12.	Peeling of skin	Over 53	60	35	16	10	5	3	5–6	8–9	Over 11 (14)	20	28
13.	Nails lost	Over 53	Over 60	53	Over 35	Over 28	Over 10	3	Over 10	Over 10	Over 11	Over 20	Over 35
14.	Transudate in pleural cavity*	35	25 (40)	18 (35)	10	5	3–4	3	3	11	5	Over 20	
15.	Heart without blood	Over 39	32–34 (40)	23	14–15	9	4	3	3	5	11	20	28
16.	Brain liquefied	35	30 (40)	(23)	14–16	5	3–4	3	3	6	10	17	28

*Volume over 500 ml.

First line: months; second line: median water temperature for the month; left column: signs of putrefaction and maceration; following columns: minimal time interval in days. If, for example, in July marbling, distension of tissues by gas, discoloration of the body, peeling of the epidermis, loosening of finger and feet nails, peeling of the skin of hands and feet, and a liquefied brain are observed, the minimum time interval of immersion would be about 2–3 days.

- (d) loss of nails
- 9. Feet
 - (a) washerwomen's skin
 - (b) loosening of nails
 - (c) peeling of skin
 - (d) loss of nail
- Internal findings
- 1. Volume of transudate in pleural cavity
- 2. Heart without blood
- 3. Liquefaction of brain

The warmer the water, the sooner a definite stage of putrefaction is achieved. From the mean water temperature for each month and the stages of decomposition, the German forensic pathologist Reh developed a chart with the minimum time intervals of immersion. Considering all 16 parameters for estimating the minimum time of immersion, the chart provided in [Table 4](#) can be used. On the left side are the useful criteria: in the first line the months, in the second line the mean water temperature, and in the following line the minimum time interval in days.

As many criteria as possible should be used for estimating the minimum time interval since death. With more than only one or two criteria, the result will become more reliable. For estimating the minimum time interval, the mean water temperature which is nearest to the actual water temperature at the time of recovery should be used. With this chart, not only the minimum time interval of immersion can be estimated but also the maximal interval by considering those criteria which have not yet developed. If in June marbling, bloating, and discoloration of the body have developed, and the nails are loose but not lost, it may be concluded that the interval of immersion is over 3 days but below 8 days. Our personal experience with this chart is quite good as it is much better than the old rules of thumb because it takes the actual temperature for the progression of putrefaction into consideration.

A recent evaluation of own cases revealed that the actual water temperatures (of the river Rhine) have risen during the last 40 years. Especially in summer, reliable results can only be expected when the actual water temperature is similar to the temperatures in the table. Therefore, for higher water temperatures, the time interval of immersion may be underestimated when using the table since systematic observations on the progression of putrefaction in correlation to the elevated water temperature are missing. Therefore, the table should be adapted to the elevated water temperatures.

Immunohistochemical Detection of Insulin, Thyroglobulin, and Calcitonin

Although morphological methods on death time estimation are of no practical value in forensic practice, there seems to be some change by the application of immunohistochemistry methods. Wehner et al. studied whether a positive immunoreaction to various antigens like insulin, thyroglobulin, or calcitonin is correlated with the time since death. The philosophy of these investigations is that with increasing PMI the tertiary structure of the antigen undergoes postmortem changes and due to protein denaturation stainings become negative.

Meanwhile, a chart was developed to give a rough estimation on the time since death by immunohistochemical methods.

Vital Reactions and Wound Healing

P Betz, University of Erlangen-Nuremberg, Erlangen, Germany

Physiology of Skin Wound Healing

Wound healing is a type of inflammation and characterized by an inflammatory response and repair processes induced by the tissue damage. These reactive changes can be divided into an initial vascular phase, in cellular reactions, and proliferative changes, which were mediated by the time-dependent appearance and disappearance of a lot of different molecules detectable in the cellular and extracellular matrix. The different phases of these tissue complex reactions were recently described in detail under forensic aspects by Cecchi.

Early Vascular Phase

Immediately after severe tissue trauma, fibrin occurs in the damaged area as a result of the clotting process. However, fibrin can be induced up to approximately 6 h after death, so fibrin detection does not unambiguously provide evidence of the vitality of a wound, even though some authors assume that vital fibrin reactions can be distinguished from postmortem ones by morphological criteria.

Every relevant tissue alteration is followed by an early vascular reaction. This forensically very interesting phase starts with an activation of endothelial cells triggered by different mediator substances such as leukotrienes, prostaglandins, nitric oxide, and plasma proteases for example. The release of these mediators leads to changes in tissue perfusion and to an enhanced vascular permeability, which enables, in particular, an interaction between the endothelium and hematogenous leukocytes. The extracellular communication is hereby related to soluble mediators such as adhesion molecules (selectins, interstitial cell adhesion molecule (ICAM)), different growth factors such as platelet-derived growth factor (PDGF), transforming growth factor (TGF), vascular endothelial growth factors (VEGFs), epithelial growth factors (EGFs), fibroblast growth factors (FGFs), and so on, vascular cell adhesion molecules (VCAMs), chemokines, and cytokines (IL-1 β , IL-6, and IL-8), which were produced by several cell types.

The cascade of cytokines also regulates the induction of cell adhesion molecules and selectins on activated endothelial cells and is, therefore, involved in the migration of leukocytes out of the vascular space. In this context, ICAM-1 acts as a ligand of the leukocyte function-associated antigen (LFA-1), whereas VCAM-1 is a ligand of the very late activation antigen 4 (VLA-4). Different selectins are responsible for the attachment of the leukocytes at the vascular endothelium. After margination, the leukocytes actively permeate the vessel wall, attracted by several chemotactic agents such as degraded proteins, complement complexes, lymphokines, leukotrienes, thromboxanes, fibrin, and fibronectin and produce for themselves mediators, for example, different interleukins or tumor necrosis factor (TNF). In addition to these cellular and extracellular localized processes, fibronectin is involved in leukocyte migration

because of its chemotactic properties but it also provides a provisional matrix for migration of the leukocytes. It is synthesized by fibroblasts, endothelial cells, macrophages, and keratinocytes and shows a high affinity to collagen subtype III. Fibronectin enhances the attachment of fibroblasts and endothelial cells and seems to be involved in angiogenesis as well as in contraction of the granulation tissue (Figure 1).

Cellular Reactions

On such a provisional matrix, in particular, polymorphonuclear (PMN) cells infiltrate, followed by macrophages, chemotactic agents such as degraded proteins, complement, lymphokines, and thromboxanes are attracted to the damaged area. The PMN cells contribute to lysis of erythrocytes and phagocytosis of necrotic tissue by the release of proteinases and lysozyme, respectively. They also influence the permeability of the capillaries.

Although the migration of neutrophils and macrophages begins simultaneously, the reduced mobility of macrophages explains their later appearance in the wound area. However, neutrophils, which predominate in the early phase of the cellular reaction, rather quickly disappear from the lesion area, so that macrophages now dominate. In addition to the process of cell infiltration, changes in the stage of cell activation occur, which can be detected by quantification of RNA and DNA synthesis. The infiltrating cells also release hydrolytic enzymes, complement, and arachidonic acid derivatives and are mainly responsible for the phagocytosis of necrotic tissue. Depending on the material incorporated, several subtypes can be identified after a few days. Lipophages show a typical foam-like cytoplasm, whereas erythrophages are characterized by the presence of incorporated erythrocytes (Figure 2).

Inside the macrophages, the erythrocytes and their hemoglobin are degraded. This degradation process is induced by microsomal hemoxygenase and siderin results. This pigment, which is blue, can be detected in Prussian blue-stained sections and it is easily distinguished from crystallized bilirubin, so-called hematoidin. In contrast to hemosiderin, this pigment seems to be quickly reabsorbed and it is infrequently seen during wound healing.

Macrophages can be divided into several subtypes with respect to their different phagocytic activities, and also according to the time-dependent expression of different immunohistochemically detectable antigens, for example, early (27 E 10), intermediate (RM 3/1), late (25 F 9), and chronic (G 16/1)-stage inflammation markers.

Although lymphocytes are mainly involved in chronic inflammation, they also play a part in healing wounds even though this is the subject of debate. Different definitions of a positive result and difficulties in distinguishing lymphocytes from neutrophils by routine histological methods may be the reasons for reported differences. Therefore, only relevant lymphocytic infiltrates should be regarded as a reactive change.

Figure 1 Lipophages in a 21-day-old lesion, HE, 350 $\times$.

Figure 2 Nonspecific esterases in a 4 h aged skin wound, 180 $\times$.

In the area of the lesion, leukocytes, mainly PMN, and activated monocytes release proteins such as monokines and growth factors that, in combination with other factors such as fibrin degradation products, stimulate the proliferation and activation of fibroblasts.

Proliferative Changes

Proliferation can be detected by demonstration of the nuclear antigen Ki 67, which is expressed in the G₁-, G₂-, S-, and M-phases of the cell cycle and also occurs during physiological regeneration. Under pathological conditions, for example, in wound healing, enhanced proliferative activity can be observed.

Cell proliferation in physiological or pathological conditions is closely associated with apoptosis. Apoptotic changes can be demonstrated by detection of the *p53* tumor suppressor gene, which arrests the cell in the G₁- or G₂-phase to enable DNA reparation. If the reparation processes are unsuccessful, *p53* initiates apoptosis and as a result, DNA fragments can be found.

Fibroblasts proliferate, and also migrate into the wound area attracted by the chemotactic properties of collagen fragments, fibronectin, complement, and lymphokines. The activation of fibroblasts is mediated by fibrin or fibrin degradation

Figure 3 Fibronectin-positive networks with infiltrating granulocytes, 3-day-old skin wound, 180 $\times$.

products, respectively, but also by growth factors, thrombocytes, and macrophages. Activated fibroblasts are characterized by enhanced enzyme activities detectable by enzyme histochemical techniques. Under forensic conditions, a time-dependent increase in the activity of adenosine triphosphatase, nonspecific esterase, aminopeptidase, and acid as well as alkaline phosphatase has been investigated (Figure 3).

Additionally, activated fibroblasts synthesize several extracellular matrix components such as cell adhesion molecules (e.g., tenascin), which are mainly expressed during embryogenesis, and also in malignant tumors and during wound healing. Owing to its typical structure-combining domains of epidermal growth factor, fibronectin, and fibrin, tenascin seems to be involved in cell migration and in the regulation of cell adhesion as well as acting as a mitogenic stimulus.

Some fibroblasts differentiate into myofibroblasts, which are contractile due to their actin content. They are involved in stabilizing and contracting the granulation tissue by the expression of different basement membrane components such as laminin, heparan sulfate proteoglycan, and collagen type IV.

Fibroblasts also synthesize proteins to replace necrotic tissue, in particular, different collagen subtypes. Collagens are proteins of the extracellular matrix with different molecular structures and are responsible for different biological functions. Collagen I is characterized by considerable mechanical properties, whereas collagen III seems to be involved in wound contraction. Collagen V participates in the migration of capillary and endothelial cells during angiogenesis and mediates cell-substrate adhesion by binding on heparan sulfate proteoglycan. Collagen VI mediates the attachment of interstitial structures in the connective tissue- and cell-binding activities (Figure 4).

At the same time, as the damaged connective tissue is being repaired, keratinocytes are stimulated and activated in order to cover the epidermal defect by migration and proliferation. Migrating keratinocytes, which also contain actin-like contractile elements, are derived from intact superficial keratinocyte layers and from adjacent skin appendages. They also use a provisional matrix of fibrin and fibronectin, which is replaced by a basement membrane after reepithelialization is complete. The basement membrane collagen types IV and VII are responsible for the mechanical stabilization of the newly built

Figure 4 Collagen VI-positive networks in a 11-day-old human skin wound, 180 $\times$.

Figure 5 Collagen IV-positive basement membranes in new forming vessels, 16 days of wound age, 350 $\times$.

epidermis, whereas laminin and heparan sulfate proteoglycan are involved in cell-cell and cell-substrate interactions. The basement membrane components are mainly synthesized by the migrating keratinocytes, in contrast to the interstitial collagen subtypes, which are produced by fibroblasts (Figure 5).

Afterward, the keratinocytes differentiate: the keratinocytes can be seen by the expression of keratin subtypes or other markers such as involucrin, filaggrin, and transglutaminase.

The initial cell-rich granulation tissue characterized by numerous fibroblasts and developing blood vessels is finally transformed into a permanent scar. During this process, enhanced apoptosis is responsible for cell reduction.

Principles of Forensic Wound Age Estimation

As discussed, every phase of the healing process is characterized by the chronologic but overlapping appearance and disappearance of several reactive changes and the time-dependent detection of these features is the basis of every wound age estimation.

Even though the age of a certain lesion cannot be determined precisely due to various factors influencing the rapidity of the reparation process, such as individual age, malnutrition,

malignant, or severe metabolic disorders, the postinfection interval of a wound can be approximately estimated by different criteria and the reliability of the statement depends on the number of evaluated parameters.

The earliest appearance of such a variable established in systematic investigations determines the minimum age of a lesion with a positive reaction. If a variable regularly occurs in a specific time interval (regular appearance), that is, such a reaction can be detected in every 'control' specimen investigated, a postinfection interval of less or more than that specific time interval is indicated. The latest appearance of a reaction can principally contribute to the estimation of advanced wound ages. However, this criterion is considerably influenced by the initial extent of the wound area and, therefore, it is of limited diagnostic value. From a practical point of view, it is almost exclusively the earliest appearance of reactive changes that is of forensic relevance since the diagnostic value of a positive finding considerably exceeds that of the negative results, which may be absent in a section of the specimen but present in other parts of the lesion.

Independent of what technique is used, one of the most important conditions for a forensically useful age estimation of wounds is a clear evidence of a positive reaction. Morphological features similar to postmortem changes are without diagnostic value.

In forensic practice, in particular, morphological features are useful for wound age estimation and they can be detected by routine histological, enzyme histochemical, or immunohistochemical techniques. Routine histological staining procedures, for example, hematoxylin and eosin staining or the Prussian blue reaction, can easily be performed but a specific and unambiguous detection of several reactive changes is not always possible. The number of variables that can be demonstrated by enzyme histochemistry is also reduced and an irregular appearance of positive findings must be taken into consideration even though the advantage can be seen in the resistance to putrefaction. Immunohistochemistry is more sensitive to autolysis, depending on the antigen investigated, but allows specific detection of numerous parameters expressed during the healing process.

Immunohistochemically detectable reactions, however, must be evaluated critically with respect to nonspecific background staining or other artifacts. Typical network-like structures distant from the wound margins and outside the bleeding zone can be regarded as positive for the immunohistochemical detection of fibronectin, tenascin, or interstitial collagens for example. Furthermore, the collagen reaction must be associated with fibroblasts because of the presence of destroyed connective tissue fibers in the damaged area. Negative as well as positive controls to prove the specificity of a reaction are necessary. Specimens showing relevant background staining cannot be evaluated.

The quality of the sections is also of very importance and it is only in optimally thin sections that a reliable evaluation is possible. In addition, a sufficient number of specimens per skin wound (in our opinion at least three specimens) must be investigated to confirm a negative finding. However, as aforementioned, conclusions based on positive findings are to be preferred. In addition, the histomorphological techniques have recently been supplemented by biochemical

Table 1 Parameters of vitality of human skin wounds (postinflammation interval <30 min)

Variable	Earliest occurrence (min)
TGF- β 1, IL-8	>1 min
P-selectin	>1 min
TNF- α positive mast cells	5
BFGF, defensin 3	10
Fibronectin	10–20
IL-1 β , IL-6, TNF- α	15–20
Neutrophil granulocytes	15–30

Table 2 Variables of shorter postinflammation intervals in human skin wounds (30 min–24 h)

Variable	Earliest occurrence
VCAM-1	30 min
ICAM-1	50–60 min
Antitriptyase and antichymase positive mast cells	1 h
Enhanced enzyme activity in fibroblasts	~2 h
Anti-27E10 positive macrophages	2–3 h
IL-1 α , IL-8, MCP-1, MIP- α positive neutrophils	4 h
Ubiquitin positive neutrophils	4 h
Macrophages > neutrophils	20 h

methods, for example, identifying metabolites of inflammation mediators, and by proteomic and genomic technologies for detecting cell stage activation markers, which can probably contribute to a more exact forensic wound age estimation in the future. The earliest appearance of actually used parameters of vitality and forensic age estimation of human skin wounds is listed up in [Tables 1–3](#).

Glossary

MinIP Minimal intensity projection.

MSCT Multislice computed tomography used instead of multidetector computed tomography.

PMCT Postmortem computed tomography.

PMI Postmortem imaging.

Introduction

Compared to antemortem forensic imaging, postmortem imaging (PMI) deals with a negative selection. The approach is different: x-ray exposure matters little. Repetition is possible. PMI shall show evidence of the cause of death and not injuries for future treatment. PMI challenges the radiologist. He must analyze the whole body and, in most cases, he knows little or nothing about the deceased's preexisting diseases, if any. The radiologist has to distinguish changes due to lethal disease from those due to nonlethal disease, and lethal from nonlethal trauma. He has to recognize causes of death and consider postmortem changes. After death, decay gas and shifting fluids form patterns, which are absent in clinical diagnostic imaging; these must be interpreted.

PMI includes radiographs, fluoroscopy, and postmortem computed tomography (PMCT). In PMCT, multislice CT (MSCT) has advantages over single-slice CT; MSCT furnishes 3D data with higher resolution. The display of 3D images has a better quality. This has advantages when the direction of an impact has to be determined and when complicated traumata have to be demonstrated.

Postmortem Changes: Gas and Fluids

Gas refers to air or decay gas. Air in the tissues indicate injuries and has to be differentiated from decay gas. Gravity and decay displace fluids after death. Gas and fluids produce patterns, which can simulate symptoms of trauma or disease.

Gas

Chemistry allows for recognition of decay gas and its differentiation from air. This analysis is only rarely available and, if available, it is time consuming and expensive. Therefore, it is profitable to use other means of differentiation. In the vessels, air and decay gas appear on radiographs as negative filling. Air and decay gas differ from each other; they show different distributions and appear at different times. These patterns are typical and permit discrimination in most cases. In cases of doubt, PMI indicates the best localization, from where the forensic pathologist can obtain the gas for analysis by puncture.

After death, decay gas is first visible in the vessels, thereafter in the cavities (pleural, subarachnoid, and peritoneal), and

last, in the parenchymal organs, the muscles, and the soft tissue. Decay gas (and air) migrates upward; therefore, it can be seen in the ventral vessels of the liver and the anterior chest wall. The differential diagnosis has to consider air embolism, and air replacing blood via a vascular opening or injury. The time until decay gas appears after death varies: in corpses without cooling, decay gas emerges earlier and in a larger quantity than in those conserved by cooling. However, late appearance does occur. These variations in time of decay gas formation make it difficult for a reliable guess about the time passed since death.

In isolated cases, decay gas filling the vessels allows for visualization of vascular pathologies, similar to postmortem pneumoangiography. Even virtual endoscopy can be performed. This is valid for pulmonary embolism, vascular stenosis, and vascular occlusion (**Figure 1(a)** and **1(b)**).

Because air and decay gas migrate upward, it is possible to fill and analyze vessels by changing the position of the corpse. In air embolism, the superior vena cava (s.v.c.) and its feeding veins are dilated. Similar dilation also involves the right heart and pulmonary artery. Air embolism may occur as a complication of skull and facial bone fractures. This means that upon observing air in the veins and in the right heart, one has to look for fractures passing through the jugular foramen, and with air in the arteries, fractures via the carotid canal must be looked for. On suspicion of air embolism, the analysis must pay attention to those vessels where the air could have passed. Pneumothorax due to trauma, gunshots, and sharp trauma is also a cause of air embolism. In clinical medicine, air embolism is known as a complication of punctures. Gas in the vessels of the heart or brain connected to a sudden death in angiography suggests an air injection. This hypothesis becomes more probable when decay gas cannot be found in other vessels, especially in those of the liver, and when the PMCT has been performed shortly after death, that is, before decay gas appears. Cardiac massage in reanimation is another cause: in cardiac massage, air can be aspirated via vascular catheters and cause air embolism. Air in the cerebral and/or cardiac vessels disappears by transport and absorption. This has to be taken into account when no air is found. This has to be expected when, after futile reanimation, hours have passed before death is declared. Shortly after death, the brain damage may be visible in PMCT and PMMRI, as would have been before death had been declared. This time window, however, is narrow.

Figure 1 (a and b) Incomplete occlusion of the right coronary artery. The coronary artery is filled with gas coming from the ascending aorta. Gas peripheral of the occlusion indicates a gas passage. PMCT. Axial (a) and sagittal (b) display.

After decay gas becomes visible in the vessels, it appears in the head (between the brain and skull), the pleural space, and the peritoneal space. In general, it appears first in the peritoneal space – a possible explanation is gas production by enterobacteria. In case of absence of peritoneal gas, this means that gas in the pleural space and in the head is probably not decay gas. In consequence, one must look for a cause of a pneumothorax or for an open skull fracture. After reanimation, a bilateral pneumothorax induces the search of air bubbles in the tissue, which indicates attempts of vascular punctures of the vena jugularis or vena axillaris. At these sites, traces of bleeding are less common.

In the tissue, decay gas appears after it has become visible in the vessels first and thereafter in the peritoneal space. This is valid for parenchyma of organs, soft tissue, and muscles. Bubbles of decay gas first become visible in the pancreas and the spleen, and thereafter in the liver, the kidney, and the lung. When these sites do not show gas, gas inclusions in the trunk wall, the soft tissue of the neck, and the extremities are likely due to trauma and not due to decay. In suspected suicide, decay gas near the wrist joint may indicate a trauma due to a self-afflicted cut.

In PMCT, gas filling of the vertebral vessels and of those of the base of the skull may mimic fractures. A correct interpretation is possible by visualizing the characteristic vascular pattern; the filling with gas of neighboring vessels is an indication. Gas filling visualizes underlying disease; gastric varices are an example.

Case Report

The corpse was dedicated to the anatomy department. It contained gas (decay gas or air) in the s.v.c. and in the right heart (Figure 2(a) and 2(b)). No gas could be found in other vessels

or in the left heart. A vascular catheter had been inserted into the right jugular vein; it passed via the s.v.c. and ended in the right atrium.

Information about antemortem treatment and underlying diseases is lacking. The fact that the corpse is dedicated to the anatomy indicates that natural death has been attested and that reanimation was not tried. Extended calcifications of the pericardium suggest cardiac disease. Little fluid in the lung excludes pulmonary edema when death had occurred. The differential diagnosis has to be made with the cardinal symptom ‘gas in the s.v.c. accompanying a central venous catheter.’ It concerns:

- Aspiration of air (resulting in air embolism), possibly in the course of cardiac massage or by faulty infusion
- Postmortem replacement of blood by air
- Decay gas postmortem

Decay gas seems improbable: gas can only be seen in the s.v.c. and its feeding vessels, in the right heart, and in the pulmonary artery. Gas cannot be found in other places, especially not in the hepatic vessels. Postmortem replacement of blood by air seems unlikely: the gas filling of the s.v.c., the right heart, and the pulmonary artery is combined with distension. In the case of postmortem replacement, these vessels would not be distended; their aspect would be that of a collapse.

Aspiration of air seems possible but is not proved: the changing pressure during cardiac massage could have sucked in air via an open catheter. However, there are no rib fractures, which are normally seen when external cardiac massage has occurred.

Fluid

Water is the main component of the extracellular and intracellular fluids, the blood, and the fluid in the cerebrospinal,

Figure 2 (a and b) Gas in the s.v.c., in the right heart, and in the pulmonary artery. Central venous catheter till the right atrium. No gas in the ascending aorta. Calcifications of the pericardium. Differential diagnosis between air passage through the catheter either antemortem during cardiac massage with thorax compression (possible) or postmortem when disconnecting the catheter (possible) and postmortem decay gas (improbable). Frontal (a) and axial (b) display.

pleural, peritoneal, and pericardial space. After death, gravity induces a displacement. Patterns result; they have to be recognized when performing PMI. Leveling occurs via connecting openings. The following are examples:

- Paranasal sinuses. Leveling occurs between fluid in the pharynx and the different sinuses, if the foramina are open. In general, there is no early opacity due to leveling between the pharynx and the cavities of the petrous bone, because the Eustachian tube is not open.
- Esophagus, the trachea, and the pharynx.
- Trachea and the bronchial system.

Fluid displacement also occurs in the parenchyma of organs. This is visible in the following:

- Lung: During the first hours after death, above the pulmonary septa, densities due to migrating fluid are visible; later, they are visible above the dorsal chest wall only. Layers occur due to fluid in the lung and pleural effusions. There is leveling between these layers and the free fluid in the trachea and the bronchi.
- Brain: Sulcus effacement, which starts in the occipital region. The brain volume increases: only early PMCT or PMMRI allows differentiation between antemortem cerebral edema and postmortem fluid shift.
- Other parenchymal organs (liver, pancreas, adrenal glands, and kidneys) and the digestive tract.
- Large vessels of the chest: The aorta shows an indentation, and thereafter the form of a trefoil. These changes are more marked after massive blood loss.

In the vessels, blood shows layers by sedimentation of erythrocytes. This is visible in the aortic arch. In the brain, the occipital sinuses and large veins emerge; the same happens with the middle cerebral artery.

In the aorta, the heart, and the pulmonary artery, postmortem thrombus formation is visible as an oval, well-defined structure. This structure is hyperdense in most cases. However, hypodense thrombi also occur. The differential diagnosis of postmortem thrombus formation concerns a preexisting embolus, especially in antemortem pulmonary embolism. If antemortem pulmonary embolism is suspected,

the morphology of the structure in question can be visualized with injecting air in the vascular system (pneumoangiography). This injection is possible via a central venous catheter. This approach can be combined with virtual endoscopy. The surface of an antemortem embolus differs from that of a postmortem thrombus.

The large thoracic vessels and the heart change their form when the water diffuses into the tissue and into the cavities/spaces of the body. In cross-section images, the aorta changes from round/oval to trefoil and collapses, the s.v.c. changes from round to oval, and the pulmonary artery narrows. These changes are marked after massive blood loss. If these changes of form are accompanied by increasing fluid in the lungs and pleural effusion, the radiologist should suggest postmortem changes. Massive fluid in the lungs and pleural effusions without changes of form is in favor of antemortem pulmonary edema and cardiac insufficiency. Massive change of form without increased fluid in the lungs indicates blood loss.

Gunshot

PMI localizes the bullet and its fragments, shows its path, and helps to recognize its size and type. In civil unrest cases, PMI may show deadly effects of 'non lethal weapons' such as rubber bullets and plastic bullets.

Localization is possible with radiographs and PMCT. This facilitates detection of a projectile displaced by blood flow (bullet embolism), gravity, and movements, such as in the digestive tract. Furthermore, PMCT shows injuries of organs. In decomposed bodies, a radiograph or a PMCT easily localizes a bullet. This localization indicates the possibility of a lethal shot. This is also valid if soft tissue injuries can no longer be proved in the decomposed organs.

Entry and exit of a bullet indicate the direction. In gunshot injuries to the head, the differentiation between entry and exit holes in flat bones is primarily based on the cratering effect in the direction of fire. In the skull, the rule of Puppe also allows recognizing both (Figure 3). This rule states that an existing fracture (due to the entry of the bullet) stops the propagation of a second fracture (due to the exit).

Figure 3 Differentiation of the entry and the exit of a bullet by Puppe's rule: When two fracture lines (arrows) of a solid surface intersect, it is possible to tell which one has been made first.

Furthermore, Puppe's rule permits one to determine the sequence of gunshots. MSCT provides images for demonstration by 3D reconstruction.

In the trunk and extremities, bubbles and blood indicate the entrance and the exit wounds. In the head and in the trunk, fractures, fragments of bones and of the bullet (dots), blood, and injuries of organs indicate the path. Air in the vessels is due to a vascular injury. It must be differentiated from bubbles in the tissue; a display with MiniP (minimal intensity projection) helps. Dots appear at a distance of several centimeters from the bullet's path. This is typical for high-velocity gunshots and contact gunshots. The bone can deflect a bullet; a special form is the tangential shot in the skull.

Radiographs and (better) PMCTs show injuries. In general, fractures are easy to recognize. In the case of metal artifacts, the base of the skull may be a problem. A thorough analysis of a PMCT is mandatory to recognize all fractures and to determine their extents. The facial bones may be a problem, too: after a shot into the mouth, PMCT shows the extension of the fractures, and vascular and cerebral injuries. 3D reconstruction permits demonstration. PMCT shows large bleedings. Their localization, quantity, and pattern reveal the source. Injuries of the heart, the lung, and large vessels may show up directly. Air in the peritoneum, the pleura, the tissue, and between the brain and skull and in the spinal canal indicates an opening to the exterior, to an air-containing organ or cavity (digestive tract, trachea, paranasal sinus, and lung). The injury itself is not always visible: for example, when the lung has collapsed after a gunshot or a sharp trauma. Gunshot-induced air embolism may be the cause of death. The gas patterns allow for differentiation between decay gas and air.

Radiographs show projectiles and their characteristics. PMCT has limits due to metal artifacts. The determination of the projectile's caliber has to take magnification into

Figure 4 Transections of a rib by a stab on the left side. Child.

account. Errors are possible. High-velocity injuries produce characteristic patterns; this is valid for disintegrating projectiles (dum dum), low velocity injuries, and coated and semi-coated bullets as well.

Rubber and plastic bullets can be lethal when they enter the brain, the chest, or the abdomen. If they are detected in PMI, a detailed analysis is possible.

The integration of the 3D data of a PMCT into a 3D data set obtained at the site of a crime gives valuable information about the sequence of the actions.

Explosion

PMI shows injuries by the blast (lung lacerations and fractures), the explosive device (fragments of the weapon, nails, and shrapnel), and secondary injuries, among others, due to destroyed buildings. Suicide terrorist attacks have provoked the possibility that bone fragments of the attackers and other victims can be forced into the victim's body. They must be recognized for further investigation (DNA and infection like HIV). In war, PMI informs about the used weapon. This affects the military planning. The use of forbidden weapons (e.g., cluster bombs) can be proved by PMI.

Sharp Trauma

Transection of the rib cartilage and of the bone indicates the applied force (Figure 4). This is valid for other structures too, such as a silicon mamma prosthesis. The sharp trauma/stab creates bubbles and bleeding; it injures organs (heart, lung, vessels, and larynx). These tracks are the base for determining the direction and the depth of the trauma. Broken-off fragments of the weapon involved, furnish additional information. Marking the wound with contrast substance has been proposed. Inspection gives the number and the localization of stabs more accurately than surface

Figure 5 (a–d) Fractures of the hyoid bone and the thyroid cartilage. Strangulation. (a) Angulation of the hyoid bone (arrow). Frontal display (b) hyoid bone with bilateral fractures of the larger horn (arrows). (c and d) Fractures of the thyroid cartilage (arrow) and the hyoid bone (arrow). 3D display, oblique projection.

reconstruction. The information as to where the stabs are, supports the radiologist in his interpretation. The analysis of local bleeding, a pneumothorax, and air in the vessels help determine the sequence of stabs and cuts. The radiologist has to differentiate between air embolism and air replacing lost blood, and he must look for defense fractures of the hand.

Suffocation and Strangulation

PMI visualizes the obstruction of the airways or injuries of the airways, especially the larynx. The radiologist has to look for fractures of the hyoid bone, the thyroid cartilage, and for ruptures of the membranes, which connect them (Figure 5(a)–5(d)). 3D display of the larynx should show the bone and the cartilage; this helps analyze the intensity of the acting forces and their direction. Air in the cartilage and in the hyoid bone indicates fractures; air between the hyoid bone and thyroid cartilage indicates membrane rupture. Injuries of the airways provoke bleeding, which can block the airways. Fractures in the cervical spine indicate

sudden flexions. Brain changes need to be visualized early; otherwise, they cannot be differentiated from postmortem changes.

Deceleration Trauma, Compression, Blunt Trauma, and Blows

Lethal traumata due to deceleration, compression, blunt force, and blows usually involve several organs and regions. In general, these are cases of multiple traumata. PMI has to visualize the injuries for determining the cause of death, and their patterns for differentiating between accidents and inflicted trauma. 3D images of the skeleton (Figure 6(a)–6(d)) demonstrate the mechanism to jurists and relatives. Modified images show the injuries of organs and the bleeding. The complexity of these injuries demands a thorough analysis; otherwise, important details are missed. This is valid for injuries of the larynx – it is advisable to examine the larynx with a 3D display visualizing the cartilage and the bones; furthermore, one has to search for air in the soft tissue and blood in the neighborhood so as to not overlook ruptures of membranes and ligaments.

Water-Logged Corpse, Drowning, and Aspiration

Water-logged corpses often display signs of decay. Decay gas is visible in the vessels, the cavities, and the tissue. Virtual endoscopy of the heart is possible. Obstructions of brain and heart vessels show up; the pathologist must verify them. Liquid in the paranasal sinus is not specific to drowning. It does not prove it – PMI demonstrates liquid in every third deceased person, with little connection to the cause of death. Foam in the trachea and the bronchus suggests aspiration; the aspiration becomes more probable when similar foam is found in the esophagus and in the pharynx. Aspiration is highly probable when silicates are visible in the trachea or the bronchi in water-logged bodies. However, the radiologist needs to have in mind that after death, the tonus change of the upper esophageal sphincter promotes the fluid exchange. An aspiration has probably occurred, when a tooth is found in a bronchus and is missing the jaw. Bubbles in the soft

tissue of the defect indicate the recent loss. Children aspirate nuts and toys, which do not show up on radiographs or even PMCT, unless radiopaque (toys).

Sudden Death

The term ‘sudden death’ informs that death has occurred suddenly, that there is no knowledge of a possible preexisting disease, and that there is no hint of a crime. PMI has the aim to reveal the cause of death and to exclude a violent death. PMCT shows cerebral and cardiac causes. Within the cranial vault, the cause of death can be parenchymal, subdural, epidural, or subarachnoid bleeding ([Figure 7\(a\)](#) and [7\(b\)](#)), extended infarction, and tumor. These lesions are space occupying; they are accompanied by swelling, incarceration, and disturbed circulation of the cerebrospinal fluid. The diagnosis antemortem edema is problematic; it is only possible, when PMCT and/or PMMRI

Figure 6 (Continued)

Figure 6 (a–d) Run over by a bus. (a) The 3D reconstruction (surface mode) shows the track of the bus wheel. (b and c) In the sagittal and frontal view, the damage to the body is apparent. (d) 3D display of the bones shows where the body has been hit (rib fractures, separation of pelvis and spine).

have been made shortly after death. A radiograph showing a knife in the head suggests a violent death.

Nontraumatic perforation of the myocardium with hemopericardium is a cause of natural cardiac death. Sometimes,

PMCT and PMMRI visualize a trail of blood in the myocardium (Figure 8(a)–8(d)). Another cause of a natural death is the ruptured aortic aneurysm in the chest and in the abdomen. A large cardiac aneurysm suggests a cardiac cause; the same is

valid in the case of calcifications of the pericardium. Such calcifications can be due to a bullet, which may have been there for decades. A bilateral pneumothorax and an air embolism are usually caused by traumata and not by natural diseases. Bolus death with obstruction of the airways is easy to see in PMCT (Figure 9(a)–9(c)).

Pulmonary embolism is rarely detectable without applying contrast substance. The embolus has no contrast difference permitting the diagnosis. Its morphology does not show up in PMCT and PMMRI unless a contrast substance is given: air injection (pneumoangiography) fills the pulmonary artery and its branches. The embolus becomes visible; its surface can be seen in virtual endoscopy. Angiography with positive contrast substance produces equal results.

Identification

The pathologist assigns bones to humans. PMI is secondary. However, PMI allows one to differentiate between human bones and animal bones. PMI helps to detect bullets and metals, even if covered by bone. Its localization hints at violent death.

In unidentified bodies, PMI is meant to visualize details allowing the identification, i.e. traces of preceding surgery with metal implants. The x-ray morphology of the paranasal sinus and the anterior chest wall varies. This offers a chance to compare postmortem and antemortem radiographs for identification. Multislice PMCT leads to a 3D data set. This data set allows producing images similar to radiographs.

Figure 7 (a and b) Intracerebral bleeding. (a) Subdural, epidural, and subarachnoid bleeding. Space occupying, the midline is displaced to the left. (b) Bleeding into the right and the left cerebral parenchyma and subarachnoid bleeding.

Figure 8 (Continued)

Figure 8 (a–d) Myocardial infarction with rupture into the pericardium. (a and b) Blood with layers in the pericardium. (c and d) Blood in the myocardium allows localizing the rupture.

These radiographs obtained with PMCT are usable for comparison. Using a curved mode, PMCT also produces images apt for comparison with orthopantomograms.

PMI may help to determine the deceased's age. The proceeding is that of age determination in the living. Radiographs (PMCT) of the left (nondominating) hand, orthopantomograms, and radiographs of the sternoclavicular joint are part of established methods. Sex determination is possible, too. In general, however, the radiologist has less experience

than the pathologist determining the age and the sex of an unknown deceased.

Case Report (Figure 10(a)–10(f))

Human parts were found (Figure 10(a)–10(e)). They had been set on fire. The police asked, whether they belonged to only one or several persons. Image fusion with radiographs showed that the two trunk parts fitted to each other; the upper and the

Figure 9 (a–c) Bolus death. The meat bolus (arrows) obstructs the airways in the larynx. (a) Sagittal view; (b) frontal view; and (c) axial view.

Figure 10 (Continued)

Figure 10 (Continued)

Figure 10 (a–k) Composing the body. (a–e) These parts were discovered in different places. They were partially burnt. (f) Image fusion, using radiographs, showed that the two trunk parts fitted to each other; the upper and the lower lumbar vertebral columns complemented one another. (g) 3D display of the upper and the lower cervical spine. They complement one another. (h) 3D display of the fragments of the upper-left arm complement one another. (i) 3D reconstruction of the head showed impacts (blows) to the front and to the back of the head. (j) Blood in the ventricles indicates that these impacts had occurred during lifetime. (k) 3D display of the hyoid bone showed a fracture of the right major horn of the hyoid. This fracture was not explained by the decapitation; it indicated additional violence.

lower lumbar vertebral column complemented one another (**Figure 10(f)**). 3D display of the upper and the lower cervical spine demonstrated the same (**Figure 10(g)**); the fragments of the upper arms also fitted to each other (**Figure 10(h)**). So the answer to the question was that the discovered parts belonged to one person only.

How death had occurred was of interest thereafter: 3D reconstruction of the head (**Figure 10(i)**) proved that there had been impacts (blows) to the front and to the back of the head. Blood in the ventricles indicated that these impacts had occurred during lifetime (**Figure 10(j)**). Gas in the cerebral vessels could have replaced the blood after decapitation. However, the analysis of the larynx, which was cut through between the hyoid bone and the thyroid cartilage, with 3D display evinced a hyoid fracture of the right major horn of the hyoid (**Figure 10(k)**). This fracture was not explained by the decapitation. It indicated additional violence.

Reanimation

Reanimation is performed after a collapse, an accident, or inflicted violence (gunshot, sharp trauma, blow). Reanimation concerns respiration (intubation or tracheotomy, ventilation by mask, or tracheal or tracheostomy tube), circulation (chest compression), and medication (vessel puncture). These different measures leave traces visible in PMI. PMCT shows these traces in detail.

Respiration

The tracheal tube can end in a bronchus, or in the esophagus; the blocking balloon can lie in the pharynx compressing the vocal cord. Two tubes can be present (**Figure 11**) – the first was left in the esophagus to facilitate the placement of the second tube.

Figure 11 Two tracheal tubes. The first tube had been left in the esophagus for facilitating the second intubation.

Air bubbles and emphysema (and bleeding) indicate injuries of the pharynx, the mucosa, and the trachea. Pharynx tubes with two balloons are supposed to be more secure than simple tracheal tubes; however, detailed analysis in PMCT shows that there is not always a free airway to the trachea.

Tracheotomy may fail. In small children, the trachea is sometimes difficult to enter. In adults, the posterior wall of pharynx can be perforated; the tracheostomy tube can end outside the lumen.

Mask ventilation and ventilation via a tube in the esophagus inflate the gastrointestinal tract (meteorism). If this is visible, the intubation probably has been difficult, even if the tube is finally in the correct position. Similarly, neck emphysema (with a tracheostomy tube in correct position) points to difficulties performing the tracheostomy. In both cases, the time span prior to ventilation might have been extended significantly.

Circulation

Chest compression fractures the ribs. Fractures of ribs 2–6 are typical. Rib 1 is normally spared. Ribs 7–9 can be fractured, too. In general, the fractures show a characteristic pattern (Figure 12(a)–12(c)); the fractures of the upper ribs are nearer to the sternum. The lower ribs may have a fractured cartilage, which is more difficult to detect even on PMCT. It is advisable to differentiate between fractures with complete interruption of the bone, and inflections showing an angulation only. These inflections are not necessarily instable. After chest compression in reanimation, gas is usually seen in the hepatic vessels. This gas appears with a distribution pattern, which is different from that of gas entering the vascular system by suction via an open vascular catheter. The latter is found in the large vessels of the upper half of the body; the liver is often spared.

Figure 12 (Continued)

Figure 12 (a–c) Rib fractures due to chest compression in reanimation. Rib one is spared. 3D view.

Medication

Vascular punctures may provoke a pneumothorax, sometimes bilateral. Bleeding may occur, too. If pneumothorax and/or a bleeding are present, the radiologist has to look for puncture traces, which are bubbles and (rarely) bleeding localized at the sites typical for punctures. A catheter outside the vessels makes interpretation easier. Always, one has to keep in mind that the preceding trauma could have provoked the pneumothorax and the bleeding. A vascular catheter in a wrong position could have hindered the passage of an infusion and of injected medicaments.

PMI and especially PMCT can be a tool for quality control. They allow evaluating the performed reanimation. They furnish information that is otherwise more difficult to obtain or cannot be obtained at all. This is valid, if tubes and catheters are removed before autopsy.

Invasive Medicine and Care

After invasive actions, PMI exhibits success and failure; this concerns the position of vascular stents and aortic valves. After endoscopy, bleeding and perforation become visible. The demonstration with images facilitate the evaluation of the procedure and to avoid complications in the future. This is also valid for treating complication. In singular cases, complications become visible; this could be either due to the invasive action or the following treatment.

PMI shows a decubitus and its extent, urinary retention, the position of a urinary catheter, and the position of a gastric tube or its malposition. Such observations may raise the

question whether a poor prognosis of a patient, affects attention and care.

The malposition of a catheter puts the patient at risk. Multiple vascular catheters suggest difficulties in their placement and limited control of their position; additional edema hints at difficulties in fluid management.

After surgery, the proceedings in PMI and clinical diagnostic imaging are similar. PMI has the advantage that there is no limiting exposure dose, and therefore, repetition is possible; on the other hand, functional imaging with contrast medium is not possible, which limits the possibilities to recognize vital parts of the myocardium.

Child Abuse, Infanticide, Neonaticide, and Stillbirth

The radiologist must look for older trauma even if a lethal trauma is apparent. Fractures of different age and unfitting for the age suggest child abuse. PMI, PMCT and PMMRI enlarge the spectrum; showing bleedings and fractures, and allow age determination (**Figure 13(a)** and **13(b)**). However, they have limitations compared to clinical CT and MRI, which allow analyzing the perfusion of organs with contrast substances.

In shaken baby syndrome, PMCT, PMMRI, and PM-sonography usually show the intracranial bleeding. PMCT is also useful to find rib fractures, mainly infractions characterized by angulation and incomplete interruption of the corticallis. These infractions result when treating the baby.

The differential diagnosis of multiple fractures of different ages concerns birth trauma, osteogenesis imperfecta, congenital malformations, and anomalies. ‘Menke syndrome’ with

Figure 13 (a and b) Bleeding infratentorial (arrows). PMMRI.

multiple extra suture bones is an example: a hereditary disturbance of the copper metabolism.

The death of a child may be planned or due to neglect. The cause of death may be obvious or obscure. PMCT allows visualizing details with possible connection to the death and demonstrating the findings. Examples are the projectile in the head, the bilateral hemotopneumothorax due to stabs, the tracheal tube in the mouth after failed reanimation, and the foreign body in the larynx after failed tracheotomy.

A stillbirth raises the question of its cause. Malformation guides the analysis; this helps to decide about future pregnancies. PMCT visualizes malformations of the skeleton. Sometimes, malformation of systems and organs can be seen, too (Figure 14(a)–14(c)). Fractures raise the question of birth trauma. Furthermore, the (re)animation of the newborn can be analyzed: Pneumothorax may be due to punctures and drainages. Air can enter the vascular system postmortem, when withdrawing a catheter or antemortem by punctures. Catheter malposition indicates the difficulties of the neonatologist. Air in the lung and air in the digestive tract indicate life after birth; however, decay gas can mimic these findings. One has to keep in mind that decay produces gas; however, fluid may migrate after death into the lung and mimic airless lungs.

Dead newborns should be examined for trauma with PMCT. In the case of postmortem deformation and decay, reconstruction of the skeleton is useful. This is mandatory if violent death is a possibility.

Case Report (Figure 15(a)–15(g))

The corpse of the baby was found in a river. The trunk had a stab wound (Figure 15(a) and 15(b)). The skeleton was intact; however, the head was deformed (Figure 15(c)). The radiologist searched fractures. Therefore, he isolated the bones of the skull for digital reconstruction (Figure 15(d)).

Figure 14 (Continued)

Figure 14 (a–c) Fractures of the left arm. A–v malformation. Death on second day after birth. PMCT. (a) Skeleton, 3D view: the left humerus is thicker than the right. There is a slight difference between the right and the left forearm. (b) Left arm, frontal view. The humerus and the ulna are too thick; they are fractured. (c) Frontal view. Upper chest with enlarged vessels (here veins) on the left suggesting an a–v malformation involving the bones and explaining the pathologic fractures.

No fracture evinced (**Figure 15(e)** and **15(f)**). The analysis of the trunk showed a fracture of the eighth rib on the right (**Figure 15(g)**).

Figure 15 (Continued)

Conclusion

PMI is a tool for the pathologist. PMCT and PMMRI show a rupture of the heart and of the aorta, cerebral bleeding, and bilateral pneumothorax as causes of death. They may exhibit additional diseases. Radiographs and PMCT localize bullets and other foreign bodies. The visualization of tracheal and gastric tubes and vascular and urinary catheters offers possibilities for quality control. PMCT's strengths lie in its ability to reveal gas: air embolism and failed punctures. The 3D data set of PMCT and PMMRI can be reviewed repeatedly. A display in 3D helps to demonstrate findings to legal persons and to relatives.

Deaths Associated with Medical Procedures

G Lau and M Wang, Health Sciences Authority, Singapore, Republic of Singapore

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Anastomosis A surgical connection between two structures.

Atelectasis Collapse of part or all of a lung.

Bariatric surgery A variety of surgical procedures performed on severely obese patients for the purpose of losing weight.

Bio-prostheses A device containing biological material used to replace missing body parts.

Cholecystectomy Surgical removal of the gallbladder.

Coronary artery bypass graft surgery A surgical procedure in which one or more blocked coronary arteries are bypassed by a blood vessel graft to restore normal blood flow to the heart.

Disseminated intravascular coagulation A pathological activation of coagulation mechanisms in response to a variety of diseases.

Embolization The blocking of a blood vessel supplying an organ that may, on occasion, be undertaken as a therapeutic procedure.

Endocarditis Inflammation of the inner layer of the heart, often involving the heart valves, usually, but not always, due to an infection.

Endoscopic retrograde cholangiopancreatography (ERCP) A procedure that uses an endoscope to visualize the bile ducts and pancreatic ducts.

Hemangioma A type of blood vessel malformation.

Hemoperitoneum A collection of blood in the abdominal cavity.

Hemostasis A process that causes bleeding to stop.

Hemothorax A collection of blood in the chest cavity.

Hysterectomy Surgical removal of the uterus.

Iatrogenic An adverse condition in a patient resulting from the activity of physicians.

Mastectomy Surgical removal of one or both breasts.

Necrotizing enterocolitis A condition commonly seen in premature infants, where portions of the bowels undergo tissue death.

Necrotizing fasciitis A life-threatening bacterial infection that destroys skin fat and tissue covering muscles.

Nephrectomy Surgical removal of a kidney.

Osteomyelitis Infection of the bone.

Percutaneous coronary intervention (PCI) Also known as coronary angioplasty. A nonsurgical method to open narrowed or blocked coronary arteries.

Percutaneous endoscopic gastrostomy (PEG) An endoscopic procedure whereby a tube is passed into the patient's stomach through the abdominal wall to facilitate feeding.

Percutaneous transhepatic cholangiography (PTC) A radiographic technique employed in the visualization of the biliary tracts, involving a transhepatic insertion of a needle into a bile duct.

Peritonitis Inflammation of the inner lining of the abdominal cavity, resulting in a collection of fluid within the abdominal cavity.

Thrombosis The process by which a blood clot is formed inside a blood vessel.

Thromboprophylaxis The practice of giving calibrated amounts of anticoagulation drugs to individuals at increased risk of thrombosis, in order to reduce this risk.

Introduction

When referring a patient to hospital, should a doctor say, 'I must warn you that the simple fact of being admitted to hospital means that you have something above a 1:10 chance of suffering an adverse event and a 1:100 chance of dying'? Richard Smith, Formerly Editor, BMJ.

An Emerging Challenge

The forensic evaluation of deaths occurring during, or following, various forms of medical and surgical intervention often presents a formidable challenge to practicing forensic pathologists who are required, perhaps with increasing frequency, to conduct medico-legal autopsies on patients who are suspected of having died from iatrogenic causes.

An iatrogenic illness is, literally, a disorder induced by, or resulting from, the activities of the attending physician. From a forensic perspective, it might be more useful to consider iatrogenic injury to be attributable to the adverse effects (including mishaps) arising from medical treatment, including various

diagnostic and invasive procedures to which a patient has been subjected and which may result in serious morbidity or death. Such unfortunate deaths usually constitute the adverse outcomes of any number of procedures undertaken with diagnostic or therapeutic intent, or often both, as in the case of gastrointestinal endoscopy, coronary angiography (often coupled with percutaneous coronary intervention (PCI)), exploratory laparotomy, or interventional radiology.

Indeed, the concept of iatrogenesis may extend considerably beyond the mere confines of the medical profession proper to include the actual and potential complications of various forms of therapy administered by the ever-expanding ranks of health-care professionals allied to medicine, as well as complementary and traditional health-care practitioners.

Under the prevailing circumstances, at least in some jurisdictions, forensic pathologists may well be required to contend with the iatrogenic potential of a bewildering array of conventional, innovative, quasi-experimental, and traditional diagnostic and therapeutic modalities (including robotic surgery, which appears to be gaining ascendancy in some areas at one extreme and moxibustion at the other). Clearly,

familiarity with the complications of all, or even most, of these procedures is impossible and it, thus, behooves the forensic practitioner to be receptive to acquiring the requisite knowledge and experience required to rise to this challenge, particularly when these matters fall outside the traditional boundaries of forensic pathology.

Caveat

It is of the utmost importance to note that not all periprocedural deaths are necessarily iatrogenic in nature. Accordingly, the attending pathologist should, at the very least, be aware of the following possibilities:

1. Death was due, primarily, to a preexisting natural disease process, or traumatic injury, for which the procedure(s) was (were) performed (e.g., a patient who dies from the very ischemic heart disease for which coronary artery bypass surgery was performed).
2. Death was due, primarily, to an underlying natural disease process (which may have been undiagnosed, clinically), other than that for which the procedure(s) was (were) performed (e.g., a patient who dies from chronic obstructive pulmonary disease or an acute myocardial infarct following a hemicolectomy for colonic carcinoma).
3. Death was due, substantively, to an underlying natural disease process, with a secondary contribution from an iatrogenic injury attributable to a procedural complication (e.g., an elderly patient with multiple, severe comorbidity comprising various potentially lethal conditions, who suffers relatively minor perioperative hemorrhage, or develops severe postoperative nosocomial sepsis).
4. Death was due, substantively, to a therapeutic/procedural complication, which may include surgical and/or anesthetic mishaps, with a secondary contribution from an underlying natural disease process (e.g., a patient with some significant comorbidity, who suffers major perioperative hemorrhage, which may or may not have been lethal in itself).
5. Death was, to a variable extent, associated with, or related to, patient-specific events (e.g., postoperative self-extubation or the self-removal of a large-bore vascular catheter).

It must be emphasized, of course, that the preceding list of possible scenarios is by no means exhaustive and that one should also be cognizant of the existence of any plausible preprocedural conditions which may have placed a patient at an increased risk of periprocedural death, such as extensive comorbidity aggravated by a drug-induced predisposition to perioperative hemorrhage (e.g., an elderly patient with a history of stroke and/or ischemic heart disease, who had been prescribed antiplatelet agents as secondary cardiovascular prophylaxis).

Accordingly, an open mind is, perhaps, the most important prerequisite which a forensic pathologist attending to a periprocedural death should possess, in order to avoid prejudging the true nature of the case at hand.

An Overview of Procedural Complications Commonly Encountered in Forensic Practice

The most common forms of periprocedural iatrogenic complications comprise hemorrhage and sepsis.

Hemorrhage

Primary hemorrhage may occur intra- or postoperatively as a consequence of slipped hemostatic ligatures, dehiscence of vascular anastomoses, or direct vascular or organ trauma.

Hemopericardium

A hemopericardium may, occasionally, complicate coronary artery bypass graft surgery, due to bleeding from defects in the vascular anastomoses (between a saphenous vein or internal mammary artery graft and the corresponding native coronary artery), which would require immediate surgical reexploration. In addition, mediastinal hemorrhage may occur in patients who have bleeding tendencies or are subjected to protracted periods of cardiopulmonary bypass. Conversely, off-pump coronary surgery, when indicated, apparently reduces the need for blood transfusion and inotropic support, as well as the occurrence of atrial fibrillation and infection.

PCI, a common form of interventional cardiology comprising coronary transluminal coronary angioplasty (PTCA), often combined with the insertion of either bare metal, or increasingly, drug (e.g., plavix, sirolimus) eluting stents (BMS, DES) to relieve severe coronary stenosis and for acute coronary events, may be complicated by intrapericardial hemorrhage due to coronary artery dissection ([Figure 1](#)) and perforation. The concomitant use of an anticoagulant (e.g., heparin) and antiplatelet agents (e.g., a glycoprotein IIb/IIIa inhibitor such as abciximab, tirofiban, or eptifibatide) may further increase the risk of hemorrhage. Interestingly, in some jurisdictions, emergency PCI is not infrequently used as a last resort in patients with massive acute myocardial infarction associated with cardiogenic shock.

Occasionally, one might encounter a completely unanticipated complication, such as an iatrogenic hemopericardium resulting from relatively simple procedure, such as the puncture of a coronary artery during fine needle aspiration of a breast lesion and perforation of the right atrium during catheter angiography.

Figure 1 Iatrogenic dissection (arrows) of the anterior descending branch of the left coronary artery, induced by percutaneous coronary intervention.

Hemothorax

The insertion of a chest drainage tube (a common bedside procedure) may, especially if a trocar is used, result in an inadvertent pulmonary puncture. Indeed, the puncture of an exceptionally enlarged or dilated heart in a patient with severe or terminal cardiac failure may occasionally occur if the tube is inserted through the left lateral chest wall.

Similarly, a central venous catheter inserted into an internal jugular or subclavian vein may deviate from its intended course (to terminate in the superior vena cava or at its confluence with the right atrium) and, instead, perforate, say, a brachiocephalic vein (**Figure 2**), resulting in a massive hemothorax or pneumo-hemothorax. Occasionally, fluids and even blood may have been infused or transfused through these misaligned central lines, with possibly disastrous consequences.

Hemoperitoneum and retroperitoneal hemorrhage

Somewhat tragically, a chest drainage tube inserted through the lower part of the right lateral chest wall, such as the seventh or eighth intercostal space, may traverse the right hemidiaphragm and puncture the right hepatic lobe, sometimes to depths of 6–8 cm, culminating in a fatal, massive hemoperitoneum (possibly accompanied by a corresponding hemothorax) which is only discovered at autopsy (**Figures 3 and 4**).

More commonly, intraperitoneal hemorrhage may complicate partial gastrectomy; colonic resection; iliofemoral arterial dissection caused by intra-aortic balloon pump insertion (for cardiogenic shock); percutaneous liver and renal biopsies (even when radiologically guided), computer/computerized tomography(CT)-guided drainage of a liver abscess, percutaneous transhepatic cholangiography and biliary drainage, laparoscopic procedures (e.g., laparoscopic cholecystectomy, nephrectomy, hysterectomy, or bariatric surgery) which are attended by the potential for trocar-induced injuries and the slippage or misapplication of hemostatic clips (**Figure 5**); and laser vaporization of intraperitoneal lesions, such as endometriotic cysts. In fact, massive retroperitoneal hemorrhage may, reportedly, arise as an unusual complication of percutaneous

Figure 2 A central venous catheter entering the right pleural cavity through a perforation in the right brachiocephalic vein.

Figure 3 An iatrogenic hemoperitoneum (with a hemothorax) caused by chest drainage tube insertion.

Figure 4 Penetration of the right hepatic lobe by the chest drainage tube, as described in **Figure 3**.

Figure 5 Apparent slippage or misapplication of two hemostatic clips which were supposed to have been applied to the stump of a renal artery in the course of a laparoscopic nephrectomy.

endoscopic gastrostomy (PEG), should an initial, unsuccessful, attempt at an endoscopically guided needle puncture of the stomach result in the iatrogenic perforation or laceration of the splenic and mesenteric veins.

Indeed, in forensic terms, the introduction of any needle, trocar, endoscope, thoracoscope, or endoscope into any region of the body, may be likened to the infliction of a 'stab wound,' albeit with explicit therapeutic (rather than malicious) intent and usually with due regard for the relevant precautions. Nevertheless, such procedures are inherently invasive and, it may be argued, carry a variable potential for inadvertently causing organ and vascular damage that is similar to that of stab wounds commonly encountered in forensic practice.

Other forms of periprocedural hemorrhage

Vascular injury (e.g., carotid artery 'blow-out') attending radical neck dissection (often accompanied by partial mandibulectomy and/or glossectomy) for advanced oral, esophageal, pharyngeal, and laryngeal malignancies (e.g., squamous cell carcinoma, neuroendocrine tumors), or even thyroid carcinomas, may result in intractable and lethal hemorrhage.

It should be noted that any form of periprocedural coagulopathy, such as disseminated intravascular coagulation (DIC), such as that induced by corrective surgery for complex congenital heart disease, the repair of an abdominal aortic aneurysm, a Whipple's operation for pancreatic carcinoma, extensive bowel resection for intestinal ischemia or infarction, and reconstructive surgery for major congenital craniofacial anomalies and necrotizing enterocolitis in premature neonates, is likely to be a predisposition for serious intra- or postoperative hemorrhage which may prove to be lethal.

Preexisting comorbidity, particularly if extensive, may also pose a similar risk. Thus, preoperative sepsis, malignancy, obstetric complications, impaired liver function, chronic or end-stage renal failure (such as that complicating diabetic nephropathy or chronic glomerulonephritis), as well as thrombocytopenia and other bleeding diatheses are frequently associated with a serious risk of perioperative hemorrhage. Also, due consideration should be given to the hemorrhagic risks associated with preoperative anticoagulation (e.g., warfarin, heparin, enoxaparin, or fraxiparine (low-molecular-weight heparins) for thromboprophylaxis); antiplatelet agents (e.g., aspirin or thienopyridines, such as ticlopidine, clopidogrel, and prasugrel, and adenosine diphosphate (ADP) P2Y₁₂ receptor inhibitors, such as ticagrelor and cangrelor) following a myocardial infarction or cerebrovascular accident.

Sepsis

It has been said that Methicillin-resistant *Staphylococcus aureus* (MRSA), a surrogate marker for hospital-acquired infections, may be responsible for up to nearly 70% of all cases of *S. aureus* bacteraemia and surgical wound infection, respectively. Nursing staff dressing wounds with MRSA may have an 80% risk of carrying the organism on their hands for up to 3 h while possibly 40% of patient–nurse interactions in intensive care may result in the transmission of *Klebsiella* and *Clostridium difficile*. Both MRSA and *Pseudomonas aeruginosa* are often implicated in postoperative respiratory infections. Indeed, multidrug resistant and newly emergent strains of pathogenic

bacteria (e.g., Vancomycin-resistant *Enterococi*, *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, and extended spectrum beta-lactamase-producing coliforms, such as *Escherichia coli* and *Klebsiella*) and fungi (e.g., *Candida*, *Cryptococcus*) are commonplace in intensive care units. Even organisms such as *Acinetobacter baumannii*, once considered to be merely an opportunistic pathogen, now often falls into the same category.

Pulmonary and urological infections

Fatal postsurgical infections commonly include bronchopneumonia and urinary tract infection, with resultant septicemia from protracted immobilization. Prolonged dependency on mechanical ventilation may also predispose to pulmonary infection, as might underlying diabetes mellitus and any form of immunosuppression resulting from the use of steroids or cytotoxic agents, or immunocompromise. Indeed, highly drug-resistant strains of tuberculosis have been known to be transmitted by contaminated bronchoscopes to cancer patients. Conversely, it is important to bear in mind that, in some instances, these infections may be developed before the operations in question, but worsened subsequently.

Peritonitis

Not infrequently, acute peritonitis from anastomotic dehiscence may complicate partial gastrectomy, entero-enterostomy, and colonic or colorectal resection (in which case, the peritoneal fluid may be feculent).

Endoscopically induced perforations may cause large bowel perforation during colonoscopy, while endoscopic retrograde cholangiopancreatography (ERCP), for the removal of biliary calculi, could result in the perforation of the duodenum (possibly retroperitoneally). Biliary tract injuries, with resultant biliary leakage, peritonitis, and septicemia may complicate laparoscopic cholecystectomy (Figure 6), with fatal consequences.

Figure 6 Perforation of the common hepatic duct (blue arrows) following inadvertent application of surgical clips (red arrow) to the extrahepatic biliary tract during laparoscopic cholecystectomy.

Chronic leakage around a PEG tube, a consequence of the intra-abdominal migration of the intra-gastric bumper, may cause localized cellulitis of the skin around the stoma and, occasionally, lead to lethal peritonitis and necrotizing fasciitis.

Other postsurgical infections

These would include spinal sepsis (e.g., bacterial leptomeningitis and epidural abscesses) following laminectomy and decompression; vertebral osteomyelitis following surgical stabilization of cervical dislocation; and acute suppurative meningitis following neurosurgery (e.g., trans-sphenoidal resection of a pituitary adenoma and open resection of a meningioma).

Life-threatening pelvic retroperitoneal sepsis, caused by *Bacteroides fragilis* and *Clostridium* species, may complicate stapled hemorrhoidectomy, presumably due to the entry of these gas-producing organisms from the rectal lumen into the para-rectal space during the firing of the stapler.

Cardiac valvular replacement operations, which may involve the excision of more than one valve at a time (e.g., both the mitral and aortic valves) and the insertion of the corresponding mechanical or bio-prostheses, may occasionally be complicated by postoperative infective endocarditis. At autopsy, the infected prostheses may bear friable vegetations, possibly accompanied by thrombosis and para-valvular dehiscence (which may also occur in the absence of an infection).

Also, the infection of indwelling vascular catheters may result in what is colloquially referred to as 'line sepsis,' although this would have to be distinguished from mere microbial 'colonization' (possibly in consultation with a clinical microbiologist or infectious diseases physician). Ultimately, whether this was the source of a lethal infection would have to be decided by way of a thorough clinico-pathological correlation in any given case.

Mention should also be made of rather mundane, yet potentially devastating consequences of assisted enteral feeding through a nasogastric tube erroneously inserted into the trachea or a main bronchus, resulting in fatal aspiration pneumonia, particularly in elderly patients suffering from neurologic dysphagia.

It might be added that, not infrequently, repeated ante-mortem (i.e., clinical) microbial cultures conducted on blood and other body fluids may have persistently yielded negative results and the same outcome may be observed with post-mortem blood cultures in certain cases of severe sepsis, including those where it is deemed to be lethal. This may be due to prior administration of broad spectrum antibiotics. In such instances, recourse to elevated serum procalcitonin levels (a largely reliable indicator of bacterial sepsis) may prove to be useful.

Periprocedural Trauma

Various invasive procedures carry the attendant risks of direct visceral trauma, which may prove to be lethal. In this respect, it might be argued that, at least from a forensic perspective, most medical procedures are, to a greater or lesser degree, inherently traumatic in nature. Thus, they may be said to represent instances of 'therapeutic trauma' or, more precisely, controlled trauma inflicted with (largely beneficent) therapeutic intent,

presumably (although not invariably) with the expressed consent of the patients concerned.

Endoscopy

Colonoscopic perforation of the large bowel could result in sudden and unexpected death, presumably from reflex cardiac inhibition, even in the absence of any significant peritoneal soiling. It appears that a possible sequence of such perforations commences with the muscularis propria, followed by the serosa and, finally, the mucosa, although serosal tears without mucosal damage have been known to occur. Similarly, iatrogenic tracheo-bronchial ruptures may, occasionally, be caused by bronchoscopy, particularly if a rigid bronchoscope had been used, or even in the course of intubation.

The potential for ERCP to cause iatrogenic acute (hemorrhagic) pancreatitis is well documented, while the insertion of a PEG may be complicated by gastric necrosis and hemorrhage (attributed to excess tension between the intra-gastric bumper and the skin attachments of the tube), gastric wall dissection, acute gastric dilatation, tension pneumoperitoneum, and bowel obstruction. Iatrogenic gastric rupture associated with the balloon tamponade (through the agency of a Sengstaken-Blakemore or Linton-Nachlas tube) for esophageal varices complicating hepatic cirrhosis have also been reported.

Aorto-esophageal fistula

The occurrence of an aorto-esophageal fistula usually results in massive gastrointestinal hemorrhage, classically preceded by an initial episode of relatively mild, 'sentinel' hemorrhage. Its iatrogenic causes include thoracic irradiation, the occasional use of a rigid esophagoscope, prolonged nasogastric tube placement, and anastomotic dehiscence after a prosthetic graft repair of an aortic aneurysm.

Obstetric procedures

Forceps-assisted delivery may sometimes be complicated by cervical or uterovaginal ruptures. Conversely, fatal perinatal subgaleal hemorrhage may, occasionally, confound instrumental (vacuum- and forceps-assisted) delivery. Indeed vacuum extraction itself may, rarely, cause iatrogenic neonatal intracranial (mostly subdural) hemorrhage arising from tentorial laceration and rupture of the dural venous sinuses.

Resuscitative injuries

A wide range of resuscitative injuries may be observed at autopsy. On the whole, these tend to be artefactual in nature and are usually attributable to vigorous cardiopulmonary resuscitation. Accordingly, they are mostly concentrated in the thoracic region (e.g., electric defibrillator pad markings, bruising of the subcutaneous tissues of the anterior chest wall and the pectoral muscles, sternal and rib fractures, hemothoraces, mediastinal bruising, cardiac rupture, pulmonary laceration, and damage to the upper and lower airways), although intra-abdominal structures may be involved (e.g., esophageal, gastric, and intestinal/mesenteric ruptures and lacerations of the liver and/or spleen). Even subarachnoid hemorrhage is not unknown. The list is endless and that almost any form of blunt-force type injury could complicate vigorous and

protracted resuscitative efforts, including thoracic vertebral fracture-dislocation in the elderly.

Ironically, it is in rare instances when an erstwhile moribund patient is 'successfully' resuscitated (in the sense that his/her circulation is briefly restored for several hours, albeit at the cost of considerable inotropic and, indeed, advanced life support) that substantial and even potentially lethal hemorrhage may emanate from the damaged organs, thereby confounding the subsequent forensic evaluation of the case.

Perioperative Embolic Phenomena

Pulmonary thromboembolism

Deep vein thrombosis often develops insidiously and massive pulmonary thromboembolism may supervene with unexpected suddenness, as early as the first postoperative week. Apart from prolonged, complete or relative immobility, the other classical risk factors include trauma, obesity, sepsis, malignancy, and pregnancy. In a minority of patients, it may present as a manifestation of thrombophilia (either hereditary, or induced by auto-antibodies). In any event, the perplexing medical dilemma which prevails in respect of venous thromboembolism is that even the institution of appropriate forms of thromboprophylaxis is attended by the ever-present risk of lethal intracranial or retroperitoneal (and occasionally pulmonary) hemorrhage. Either outcome may, in turn, carry rather unpleasant medico-legal consequences which may ensue in their aftermath.

Fat and bone marrow embolism

Fat embolism may complicate surgical operations on fatty tissues (e.g., mastectomy), steroid injections, spinal and orthopedic surgery (e.g., vertebroplasty for osteoporotic vertebral collapse, total joint replacement operations), and tumescent liposuction. In contrast to fat embolism, which may be pulmonary or systemic in distribution, concomitant bone marrow embolism tends to be restricted to the pulmonary circulation. Notably, mild pulmonary fat and bone marrow embolism may represent artifacts of resuscitation.

Pulmonary cartilage embolism

Iatrogenic pulmonary cartilage embolism may present as a rare complication of orthopedic surgery (e.g., humeral fracture followed by open reduction and internal fixation), but may also be a consequence or artifact of cardiopulmonary resuscitation. Its occurrence should be distinguished from the potentially lethal condition of fibrocartilaginous embolism resulting in spinal cord infarction or acute myelopathy.

Air embolism

Air embolism may complicate head and neck operations (e.g., neuro- and thyroid surgery), where a breach in the internal jugular and, possibly other, veins in the neck may result in the entry or suction of air into the venous drainage and, ultimately, the cardiac chambers. Procedures involving central venous access (e.g., the infusion of total parenteral nutrition or hemodialysis through the subclavian or internal jugular veins) may also be attended by a similar risk.

Cholesterol embolism

Cholesterol embolism (causing acute renal failure and, possibly, multi-organ involvement, accompanied by marked eosinophilia) may occur in patients with generalized atherosclerosis, hypertension, diabetes, and aortic aneurysm, undergoing angiography, anticoagulation, thrombolysis, and any form of vascular surgery (e.g., coronary artery bypass grafting, repair of an abdominal aortic aneurysm).

Iatrogenic foreign body embolism

Examples of this category of rare phenomena include suture embolism to the left anterior descending coronary artery, following mitral valve replacement surgery, occlusion of the left coronary artery by a fragment of a femoral artery during PTCA, systemic 'meat and vegetable' embolization to the heart, kidneys, and brain arising from an esophageal-atrial fistula caused by a nasogastric tube, and intra-cardiac embolism of a distal fragment of an indwelling central venous catheter to the right ventricle and pulmonary trunk, presumably culminating in a fatal cardiac arrhythmia.

Occasionally, neuroradiological procedures, such as the therapeutic embolization of extra- and intracranial vascular lesions, such as a large facial hemangioma, by way of the introduction of polyvinyl-alcohol particles and gelfoam suspended in radiocontrast media through the right external carotid artery and facial arteries, may be complicated by fatal cerebral infarction. In such an instance, it is thought that some of these particles may have entered the cerebral circulation through naturally occurring anastomoses between the external and internal carotid arteries (Figure 7).

Complications Associated with Solid Organ Transplantations

A detailed description of the various long- and short-term complications arising from solid organ transplantation as well as allograft rejection issues is beyond the scope of this article. Only a brief summary of the common anatomical complications which might be encountered in the course of a forensic autopsy on a deceased patient who had undergone

Figure 7 Birefringent foreign body emboli in the cerebral microvasculature: a complication of therapeutic embolization of a facial hemangioma (H&E, polarized $\times 400$).

liver, renal, and heart transplants (which are among the most common form of organ transplant operations) are presented here. In all of these instances, it is hardly surprising that the most common cause for sudden cardiovascular collapse in the early postoperative period is hemorrhage, either consequent to hemostatic failure due to issues concerning the application of surgical staples or sutures, or due to existing DIC.

Liver transplants

In liver transplantations, the postoperative mechanical complications relating to the hepatic artery include acute thrombosis, luminal stenosis, pseudoaneurysm, and arteriovenous fistula. Disruption of the hepatic artery flow results in biliary ischemia, with subsequent biliary strictures, bile leaks, biloma, infected bilomas, and frank intrahepatic abscesses. Hepatic infarction, fulminant hepatic failure, and bacteraemia may also occur. Causes of hepatic artery thrombosis include allograft rejection, hepatic artery kinking due to vascular redundancy, and technical problems at anastomosis. Hepatic artery stenosis can be caused by clamp injury, intimal injury due to perfusion catheters, anastomotic ischemia due to a disrupted vasa vasorum, and rejection. Hepatic artery pseudoaneurysm can occur at the extrahepatic portion, usually at the donor–recipient arterial anastomosis. They are usually caused by infection or technical failure and carry the potential for rupture and life-threatening hemorrhage.

Early bile duct strictures at the anastomosis may result from technical difficulties or by fibrosis and scarring associated with bile leaks. They can also be related to marginal blood supply of the cut ends of the donor and recipient ducts. These can give rise to rapid onset of allograft dysfunction and sepsis. Portal vein stenosis and thrombosis, usually at the anastomotic site and extrahepatic segment, can result in graft dysfunction and portal hypertension. The usual causes include surgical difficulties, excessive vessel redundancy, and hypercoagulability. The development of post-transplantation inferior vena cava stenosis or thrombosis is uncommon. Causes include technical problems, inferior vena cava compression due to fluid collection or a hematoma, and a mass effect from hepatic regeneration. This can lead to the development of the Budd–Chiari syndrome comprising pleural effusion, hepatic enlargement, ascites, and lower limb edema.

Renal transplants

Early post-renal transplantation complications that the forensic pathologist may encounter include thrombosis or stenosis of the renal vessels and urine leak or obstruction at the ureteric anastomotic site.

Renal artery thrombosis generally is an early complication of the immediate post-transplant period, though it may present later. It is caused by a low perfusion from hypotension or vascular kinking due to technical difficulties. This may present as sudden cessation of urine output, and the likely outcome is graft loss. Renal vein thrombosis is also typically an early complication manifesting as graft tenderness and edema, with the patient experiencing dark hematuria and diminished urine volume.

Urine may leak from the anastomotic connection of the ureter to the graft, resulting in a perigraft fluid collection which may be infected and/or give rise to graft dysfunction.

On the other hand, late post-transplant ureteric obstruction may be consequent to hematuria or chronic fibrotic changes at the anastomosis site or due to extrinsic compression from urinoma, hematoma, or lymphocele. The graft becomes distended and edematous with ensuing hydronephrosis.

Cardiac transplants

The surgery of cardiac transplantation has many complications similar to those of other open heart procedures. These include hemorrhage from suture lines at the vascular cannulation sites for cardiopulmonary bypass or the various anastomotic sites between donor and recipient vessels and atrial walls, cerebral infarction, and acute donor heart infarction due to prolonged perioperative ischemia.

Anesthetic Complications

Anesthesia with mechanical ventilation may be attended by impairment of gaseous exchange, leading to decreased blood oxygenation. Indeed, atelectasis is said to occur in 85–95% of patients, often immediately after induction of general anesthesia, affecting some 20–25% of basal lung tissues.

However, significant anesthetic mishaps seem to occur at a much lower frequency than primarily operative complications, but often carry devastating consequences. Accordingly, while anesthesia might contribute to death in 1:1700 operations, probably not more than 1:10 000 patients die exclusively from an anesthetic complication. It might be added that surgeons and anesthetists/intensive care specialists may differ quite sharply on the surgical mortality risk presented by a patient, especially one who is severely ill or is erstwhile stable, but has extensive, severe comorbidity.

The following events may be encountered in forensic practice:

1. Oxygen deficiency culminating in hypoxic-ischemic encephalopathy (e.g., failed intubation, dislodgement of the endotracheal tube, faulty connections, and prolonged reversal).
2. Intraluminal airway obstruction by blood, mucus, or a foreign body (e.g., a piece of gauze).
3. Extrinsic airway obstruction by mediastinal mass lesions (e.g., thymoma, thymic carcinoid, and germ cell tumors; large B-cell, lymphoblastic and Hodgkin's lymphomas), where life-threatening or lethal tracheo-bronchial compression supervenes, with resultant respiratory distress during intubation and induction of anesthesia, or even after extubation, with the combination of muscle paralysis and the supine position conspiring to impede respiratory movements of the thoracic cage (**Figure 8**).
4. Aspiration of regurgitated gastric contents or contrast medium.
5. Prolonged or excessive neuromuscular blockade. Thiopentone, which is used in induction, may cause cardiorespiratory failure, while trichloroethylene and premedication with atropine may result in sudden circulatory failure.
6. Malignant hyperthermia, a rare, autosomal dominant condition (with an estimated incidence of 1:5000–1:70 000) which predisposes the patient to sudden uncoupling of oxidative phosphorylation, with the resultant

Figure 8 A clinically undiagnosed mediastinal tumor (diffuse B-cell lymphoma) encasing the aortic arch and the associated major arteries, contributing to post-anesthetic death.

massive overheating, induced by exposure to certain muscle relaxants (e.g., suxamethonium) and halothane.

7. Halothane hypersensitivity (at an estimated incidence of 1:6000–1:600 000), with halothane-induced hepatitis, or even resultant massive hepatocellular necrosis, usually after repeated exposure to the agent. There is evidence that it is mediated by the immune sensitization of susceptible individuals (carrying CYP2E1) to trifluoroacetylated liver protein neoantigen formation resulting from oxidative halothane metabolism.
8. Isoflurane has also been reported to cause fatal massive hepatocellular necrosis after a second exposure to this supposedly nonhepatotoxic alternative to halothane in a woman with a history of alcohol use and mild obesity. Instances of enflurane-induced hepatotoxicity have also been reported (167).
9. Propofol, a sedative-hypnotic agent used for the induction of anesthesia and for sedating mechanically ventilated patients in intensive care units, has been associated with fatal cardiac failure, both in children and in adult head-injured patients. In fact, the constellation of myocardial failure, metabolic acidosis, and rhabdomyolysis in children receiving propofol infusions for >48 h has been termed the propofol-infusion syndrome. In addition, propofol has been known to induce hypertriglyceridemia which may, in turn, predispose a patient to necrotizing pancreatitis.
10. Iatrogenic cervical dislocation has been reported in children undergoing lymph node biopsy under general anesthesia. Rotation of the head and neck during the procedure is believed to have caused atlanto-axial rotary dislocation, requiring neurosurgical intervention (open reduction). From a forensic perspective, it is not at all difficult to appreciate that this is a potentially life-threatening complication.
11. In some instances, intra-operative hypothermia may supervene. It has been demonstrated that maintaining perioperative normothermia could reduce the risk of hemorrhage, wound infection, and acute cardiac events

this being particularly emphasized for patients with cardiac risk factors. It is conceivable that there might be occasions when such factors might have to be taken into account when conducting a perioperative autopsy.

12. It has been suggested that common foods, such as potatoes, tomatoes, and aubergines, may contain naturally occurring solanaceous glycoalkaloids (which are naturally occurring insecticides that remain in the body for several days after ingestion) that, even in small quantities, may inhibit butyryl cholinesterase and acetylcholinesterase, resulting in the persistence of anesthetic agents and muscle relaxants in the body and, thus, a longer recovery time of as much as 5–10 h. The potentially lethal consequence of this largely unanticipated, if rare, complication is self-evident.

Nonanesthetic Causes of Iatrogenic Hypoxia

Iatrogenically induced hypoxia may occur in settings which are not related to anesthesia. Profound hypovolemic, septicemic, cardiogenic, or neurogenic shock, as well as cardiac arrhythmias may lead to protracted cardiorespiratory arrest and resultant hypoxic–ischemic encephalopathy.

Indeed, oxygen desaturation is known to occur even in less dramatic situations, as for instance, during upper gastrointestinal endoscopy (e.g., esophago-gastroscopy, ERCP) performed under sedation, at an incidence estimated at 55–91% and associated with a mortality risk of ~1 in 2000 procedures.

Even common and usually mild therapeutic complications may have lethal consequences when the latter present with exceptional severity. In one instance, extensive post-extraction hemorrhage into the floor of the mouth, larynx, and cervical muscles, following upon the extraction of an impacted mandibular molar, caused fatal mechanical asphyxia.

Similarly, Ludwig's angina, a life-threatening, diffuse infection of the submandibular and sublingual spaces, caused by various Gram-negative organisms, as well as *Streptococcus viridans*, *S. aureus*, and *S. epidermidis*, may spread inferiorly to cause mediastinitis, empyema, pericarditis, and pericardial tamponade. Apart from sepsis, it can also cause critical airway obstruction requiring tracheostomy. While dental abscesses, intravenous drug abuse, and pharyngo-tonsillitis are the usual etiological factors, it may occasionally complicate dental extraction.

The Forensic Evaluation of Periprocedural Deaths

The Postmortem Examination

The undertaking of an impartial and meaningful forensic evaluation of a periprocedural death would, quite naturally, be centered on the findings of a thorough postmortem examination. In this respect, the attending forensic pathologist may wish to take note of the following matters:

1. Comprehensive clinico-pathological correlation is usually indispensable to the process, as it enables the autopsy findings to be interpreted in the appropriate clinical context. In forensic terms, this may be regarded as being analogous to a correlative analysis of the autopsy findings relative to the

scene and circumstances of death in any other form of medico-legal death investigation.

2. An awareness of the corresponding medico-legal implications of the case in question is essential. The mere occurrence of an iatrogenic injury, even if patently demonstrable at autopsy, does not, in and of itself, necessarily signify negligence on the part of the attending clinician(s) or operator(s).
3. The inestimable importance of preautopsy review of the relevant medical records pertaining to the case at hand cannot be over-emphasized, as this would enable the attending pathologist to identify the key clinico-pathological and medico-legal issues of concern that would largely determine the manner in which the autopsy proper is to be conducted. In this context, it must be said that performing a periprocedural autopsy without the benefit of being guided by the clinical records is a most unwise venture which is likely to result in a woeful misinterpretation of the autopsy findings. Indeed, the unwary pathologist may very well encounter preventable technical difficulties in the course of the autopsy should he decide to proceed 'blind.'
4. Both pre- and postautopsy consultations with clinical colleagues in the relevant specialties or subspecialties, who are unconnected with the case at hand, may very well be in order, particularly when one is faced with a complex periprocedural death following a series of operations, or an unusual procedure. At the very least, this would afford the attending pathologist with a reasonable understanding of the indications and complications of these procedures and their associated risks of mortality.

Conduct of the Autopsy

The purpose of a periprocedural autopsy obviously consists of ascertaining the medical cause of death with particular reference to the following issues:

1. Whether an iatrogenic injury had occurred and is demonstrable at autopsy, or by means of the relevant ancillary investigations.
2. Whether an iatrogenic injury, if present, is likely to have been the primary or substantive cause of death.
3. Whether an iatrogenic injury, if present, is likely to have been a contributory, rather than the substantive, cause of death.
4. Whether an iatrogenic injury, if present, had a negligible contribution to the causation of death.

It should be noted that the answers to these questions are by no means easily elicited, in view of the fact that the altered anatomy resulting from various and, not infrequently, multiple, surgical, and other invasive procedures could confound the autopsy itself. Indeed, an iatrogenic injury (e.g., a surgically induced intestinal perforation) which might have been documented in the clinical records could have healed, or perhaps no longer demonstrable as the affected organ, or part thereof, had been resected or excised prior to the patient's demise. Consequently, it might be advantageous to the attending pathologist to secure the attendance of the principal operators (particularly surgeons, endoscopists and interventional cardiologists and radiologists) at periprocedural autopsies.

Moreover, irrespective of whether morphological evidence of such a therapeutic complication is discernible at autopsy, one is often obliged to address the critical question of whether it actually played a significant role in causing the patient's death. This issue may be extremely perplexing especially in instances where the patient had, with the aid of intensive care, advanced life support (including mechanical ventilation and the administration of inotropic agents), as well as repeated surgery, interventional radiology, and other means, managed to withstand the deleterious effects of various iatrogenic complications for protracted periods of time, possibly in the order of many weeks, months, or even in excess of a year, before succumbing to other complications, such as sepsis, venous thromboembolism, and multi-organ failure. Under such circumstances (which is by no means uncommon in some jurisdictions), the increasing temporal remoteness between the occurrence of an iatrogenic injury, however life-threatening or potentially lethal it may have been, and the eventual demise of the patient would have very considerably weakened the putative causal relation between both events.

In conducting a periprocedural autopsy, the attending pathologist would be well served to note and document the following features and processes, which should be clearly reflected in the corresponding autopsy report:

1. The location, dimensions, and condition of the marks of recent and previous operations (e.g., surgical incisions and scars, injection and puncture marks, as well as evidence of healing, dehiscence, or infection at these sites). Where possible, it is good practice to avoid incising along, or across, existing surgical incisions, so that they can be examined in their original state. It may also be necessary to examine, *in situ*, various organs and anatomical structures which had been subjected to surgical alteration, prior to their evisceration.
2. The placement of various medical devices, tubes, catheters, and drains (e.g., esophageal as opposed to proper endotracheal intubation (Figure 9), proper cannulation of a central venous catheter as opposed to misplacement (Figure 10) or venous perforation and proper placement of a chest drainage tube as opposed to the iatrogenic perforation of a lung).
3. Performing an *in situ* examination of the anatomical structures in and around the operative site(s), to detect or exclude the presence of suspected dehiscence of vascular, gastrointestinal, biliary, or other surgical anastomoses (e.g., following a repair of an aortic aneurysm, a hemicolectomy with an ileo-colic anastomosis, or a hepatico/choledochojejunostomy created in the course of a Whipple's operation or liver transplant). Similarly, where appropriate, *in situ* examination of the stumps of surgically divided blood vessels should also be undertaken in order to ascertain the integrity of hemostatic ligatures and, increasingly, clips which had been applied to them, in the course of the operation (e.g., apparent slippage of a hemostatic clip from a renal artery following a nephrectomy). Obviously, this part of the examination should be undertaken prior to the evisceration of the internal organs, in order to prevent artefactual damage to delicate and, possibly friable, surgically altered anatomical structures and any dislodgement hemostatic devices (or subsequent

Figure 9 Esophageal intubation.

Figure 10 A misplaced central venous catheter deviating into the left subclavian vein.

allegations thereof, as the ensuing legal proceedings in these cases may be extremely contentious, indeed).

4. The sampling of the relevant tissue and body fluid samples for the relevant ancillary investigations, including post-mortem histology (which may be crucial in establishing a clinico-pathological correlation (**Figure 11**), or, in some instances, ascertaining the proximate cause of death from

Figure 11 Disseminated intravascular coagulation: fibrin thromboemboli in the glomerular capillaries (H&E $\times 200$).

acute myocarditis, massive hepatocellular necrosis, or tubulo-interstitial nephritis); toxicology (to confirm to exclude periprocedural medication errors, which may require the analysis of antemortem blood samples, particularly if death had occurred after a lapse of some days or weeks); postmortem serology, microbiological examination and molecular analysis, where indicated, to detect the presence of various bacterial, fungal, and viral pathogens believed to have been responsible for causing lethal postoperative sepsis; occasionally, postmortem angiography to evaluate the possibility of air or gas embolism, or to assess the integrity and patency of vascular (coronary or peripheral arterial) bypass grafts, as well as that of their respective anastomoses, and the localization of endovascular stents.

In addition, photographic documentation of the relevant pathology and iatrogenic injuries may serve to provide a permanent, visual record of the various significant features detected in the course of the autopsy. This may be particularly useful in instances where the sheer complexity of these features may, occasionally, defy precise and comprehensive description, although it behooves the attending pathologist to endeavor to do so in all circumstances.

Postautopsy Evaluation

The autopsy report may be regarded as being, primarily, a precise and appropriately comprehensive statement of fact, describing the findings of the postmortem examination in full. Here, it is held that, where possible, it should also provide a neutrally worded interpretation of all the postmortem findings, including those derived from the relevant ancillary investigations.

Certainly, a forensic pathologist should refrain from expressing opinions on matters pertaining to the propriety of the patient's clinical management, simply because the former is not a clinician and also in view of the highly subspecialized nature of contemporary medical practice. Nevertheless, it may be argued that he has a professional obligation to identify and raise issues of medico-legal concern to the proper authorities under whose direction the postmortem investigations were undertaken. Indeed, these matters, which may have to be

addressed by the relevant clinical specialists, either in an appropriate judicial setting (e.g., a coroner's inquest), or a medical forum (e.g., departmental morbidity and mortality discussions), may contribute substantially to medical audit and patient safety. Naturally, there are limitations to what a postmortem examination, however thorough, may accomplish and it must be acknowledged that electrolyte disturbances and coagulation and platelet defects are best assessed by having recourse to the clinical data.

Indeed, situations may arise where it would be advantageous, if not essential, to have recourse to external expertise to conduct technical evaluations of various medical devices, such as anesthetic machines, laparoscopes, surgical lasers, robotic surgical appliances, and hemostatic devices, in order to determine if equipment failure might have caused or contributed to the occurrence of a fatal iatrogenic complication.

Classification

At the conclusion of what is often a rather protracted and, one might add, tedious evaluative process, any particular periprocedural death which warrants a detailed medico-legal or forensic investigation may expediently fall into one of the following categories:

Category A: Deaths in which the postmortem examination reveals an unequivocal morphological cause of death, quite independently of the patient's clinical history. These cases, it may be said, are increasingly rare. An example would be sepsis or organ perforation resulting from the inadvertent retention of surgical devices (e.g., sponges, gauze, and towels, which may give rise to *gossypibomas* – essentially masses within a patient's body comprising a cotton matrix encapsulated by foreign body granulomata; scalpels, artery forceps, and so on), which must be distinguished from those which were intended to be left *in situ* for a variable period. Other eminent examples would be fatal hemorrhage from the open stump of a blood vessel arising from hemostatic failure, or the insertion of a chest drainage tube into a lung or through the right diaphragmatic dome into the liver.

Category B: Deaths wherein plausible morphological causes of death were discernible at autopsy, but where comprehensive reviews of the relevant clinical records were essential for a proper evaluation of the temporal and causal relations between the procedural interventions undertaken and the associated pathology. Examples include postoperative hemorrhage or suppurative meningitis following upon the trans-sphenoidal resection of a pituitary tumor, sepsis, DIC, and multi-organ failure supervening after bowel infarction and perforation after colonoscopy, or even the more mundane instance of massive pulmonary thromboembolism complicating deep vein thrombosis (which may have been undiagnosed, clinically) after practically any form of surgery, where multiple risk factors including some form of preexisting thrombophilia (e.g., Factor V Leiden) may have predisposed the patient to its development. Notably patients, whose deaths fall within this category, tend to have extensive and serious or life-threatening comorbidity, including chronic organ failure.

Category C: Cases which would inevitably require detailed clinico-pathological correlation to formulate the causes of death, in the absence of unequivocal, or demonstrable, morphological causes of death. Prime examples of such cases comprise situations where the anatomical structures which had

sustained various forms of iatrogenic injury (e.g., a segment of the small or large bowel which was inadvertently perforated in the course of adhesiolysis, or a previously dehiscant ileocolic anastomosis of gastro-jejunostomy) had been resected or removed during further exploratory or corrective surgery. Recourse to the antemortem histopathology (anatomical pathology) reports on the resected surgical specimens may be useful in the postmortem evaluation of these cases. The forensic evaluation of these cases also tends to be confounded by the coexistence of extensive and serious comorbidity.

In all probability, a majority of cases (possibly $\geq 50\%$) would be placed in the last category, thus emphasizing the importance of clinico-pathological correlation in the forensic evaluation of periprocedural deaths.

In some jurisdictions where periprocedural autopsies are conducted routinely, forensic pathologists with a philosophical bent may marvel at the fact that major surgery – sometimes a series of extensive operations requiring general anesthesia – is actually conducted on some severely and chronically ill, elderly patients, each with myriad comorbidity involving almost every major organ system. In such instances, the apparent value of the autopsy would be to demonstrate, morphologically, that any of these conditions would have been sufficient in the ordinary course of nature to cause death, but that the peri-operative complications which (inevitably) supervened, arguably constituted a *novus actus interveniens* which abruptly converted what would otherwise have been death from natural causes to an iatrogenic one.

Conclusion

There can be no doubt that the postmortem examination and forensic evaluation of a periprocedural death, with all its inherent clinico-pathological and medico-legal complexities, is often onerous and may well stretch the attending pathologist to the very limit of his or her professional capacity, endurance, and patience. Moreover, as the preceding overview of periprocedural complications clearly illustrates, the iatrogenic potential of a medical procedure is not merely limited by its invasiveness, but is often heightened by a variety of adverse drug reactions associated with them.

Nevertheless, in embracing this vast and fascinating subject – which is, essentially, boundless in its manifestations – forensic pathologists may help to bring about some measure of closure to these perplexing events and make a significant contribution to medical audit and, ultimately, patient safety. This may be regarded, as it were, as a natural extension of the more traditional role of enhancing occupational, transportation, and general public safety that forensic pathology has played in the past and, indeed, continues to fulfill (albeit often unacknowledged).

At the very least, forensic pathologists who have the privilege of engaging in this aspect of medico-legal death investigation, should be immensely grateful to their clinical colleagues for supplying them (intermittently or endlessly, as the case may be) with the intellectual stimulation which, it may be said, is so very vital to their continuing professional development.

Perhaps a fitting conclusion to this section on deaths associated with medical procedures would be the following

quotation from the *Father of Morbid Anatomy*, the late Giovanni Battista Morgagni (1682–1771):

Those who have dissected or inspected many bodies have at least learned to doubt, while those who are ignorant of anatomy and do not take the trouble to attend to it, are in no doubt at all.

Glossary

DNA Deoxyribonucleic acid: restriction fragment length polymorphism.

Forensic science is the application of sciences pertaining to the law. It requires the complementary interaction of a wide range of scientific specialties and disciplines. The term ‘criminalistics’ is often used interchangeably with the term forensic science. According to the American Board of Criminalistics, criminalistics is defined as the profession and scientific discipline directed to the recognition, identification, individualization, and evaluation of physical evidence by application of the physical and natural sciences to law–science matters. The history of forensic science – i.e., applying ‘scientific’ principles to legal questions – has a long and intriguing history.

One of the oldest known reference to a specific forensic case-solving method dates back to the Chinese Qin dynasty (721–707 BC). The account of this case was found in a bamboo tablet, which was, in turn, found in a tomb. The tablet’s contents refer to ‘examination of tangible proof regarding serious offenses.’ However, before such a legal and scientific basis was used to solve cases, evidence was assessed and retained in immaterial, esoteric, magical, or spiritual ways, which varied from one society to another. Even institutional evidence has long been under the influence of religions and beliefs. Evidence was often drawn from God’s judgment: through certain tests, a person

suspected of a crime was found guilty or innocent. For instance, the judicial duel and the cross ordeal made it possible to decide between two opposed parties, by assuming that God had given his support to the winner of the test. Whenever only one person was suspected of a crime, other ordeals determined, through various physical tests, whether that person was guilty or innocent according to the success or failure of the test. Evidence through God’s judgment is found throughout history, in Hammurabi’s code of laws in Mesopotamia, in ancient Egypt, or in Europe with the Franks and the Burgondes.

Despite its godly origin, this method of obtaining evidence turned out to be limited, and societies turned to confession and testimony in order to prove offenses. This type of evidence, however, which requires that the culprit acknowledge his or her offense, is deemed so important that it is implemented through complex, detailed, and formal procedures.

At the same time, experts were increasingly consulted to enlighten certain aspects of a case. Thus, ‘barbers – physicians’ were required to give their opinions on the circumstances of someone’s demise: for example, to establish whether the decedent could have been poisoned or if the decedent’s body bore suspicious traces. Weapons manufacturers were sometimes

used in a similar way. As early as the sixteenth century, a guild of handwriting experts was created in France to provide courts with their analysis regarding forgery issues. Even if confession and testimony were the outcome of crime investigation and remained at the heart of criminal proceedings, technical and scientific expertise was introduced in the trial out of necessity. In the eighteenth century, the United States of America started resorting to experts 'with a specific training and background' that jury members could not have.

Thus, there was a progressive rise of the technical and scientific field on the legal scene; however, this expertise was used to support evidence obtained through confession, not to replace it. Moreover, each technical and scientific discipline followed its own path with no regard to others, thus building up walls, which still exist in many countries, such as the one between forensic pathology and forensic sciences.

During the second half of the nineteenth century, under the influence of a group of forensic pathologists and scientists, a new set of ideas and common views about forensic science and the law were introduced. Young industrial societies were not satisfied with confession anymore: sciences had to break into the investigation process and the criminal trial in order to reinforce the judicial system. These pioneers spread forensic sciences thanks to a criminological approach and the issue of crime repetition (also known as recidivism).

Because legal systems then in force were already harsher toward second offenders than first ones, identifying second offenders was a major issue. Alphonse Bertillon was hired in the 1870s by the Paris police department as a book-keeper to write down criminal facts, names, and a brief description of the arrested suspects. He quickly realized that the same people were frequently arrested by the police department under different names. Using his father's work as an anthropologist (doctor Louis Adolphe Bertillon was a professor at the Paris School of Anthropology), Alphonse Bertillon noticed the wide range of body measurements among individuals. He then created a system of measurements and photographs in order to identify second offenders. This system was tested within the Paris police department from 1882 onward and officially set up in 1888, almost 10 years after it was created. Afterwards, criminal anthropometry was implemented all over the world and Bertillon's method had its hour of glory.

Bertillon also introduced criminal photography on crime scenes, which drastically changed the way crime scenes were dealt with. The crime scene was no longer ephemeral, it was engraved on photographs, thanks to which traces left on the crime scene could be tracked, recorded, and used. According to Bertillon, one should only rely on physical clues. Many works were carried out, starting in Europe, and contributed to building modern forensic sciences.

In Austria, Hans Gross, an Austrian judge, imposed training in forensic sciences upon lawyers, and, in particular, upon examining magistrates ('juges d'instruction') as early as 1893. His work was particularly advanced in its design and displays. His training provided judges with an overall view of forensic sciences, from scientific investigations to forensic analyses. Gross always took as a starting point the reconstruction of the crime scene. He was the one to introduce the word 'criminalistics.'

In Italy, from 1876 Cesare Lombroso led the way for a whole research movement. Doctor Salvatore Ottolenghi covered a wider scientific range (forensic pathology, identification, anthropology, fingerprints, and a large part of psychology). In 1896, he set up a class of 'polizia scientifica' and in 1902, he created a 'scuola di polizia' (a police academy).

Lombroso's work was questioned by the Lyon school of thought, which included Alexandre Lacassagne, a forensic pathologist, and its student Edmond Locard. They denied any scientific value to stereotyped interpretations (such as considering any person with a tattoo on their skin as a potential offender) and more generally rejected the born criminal theory. While Bertillon had not yet started his job within the Paris police department, Professor Alexandre Lacassagne combined modern forensic pathology to forensic sciences thanks to the range of his research work. Head of the 'Criminal Anthropology Journal' from 1895 to 1914, he displayed his influence and his will to gather all fields of new knowledge. Doctor Edmond Locard was the greatest example of the necessary combination of forensic pathology and forensic sciences. In 1910, he founded his own laboratory in the attic of Lyon's law court and named it 'Anthropological and criminal expertise unit.' He is recognized for the inception of the Locard exchange principle: 'Every contact leaves a trace,' the basic tenet of forensic sciences.

In Switzerland, Rodolphe Archibald Reiss took on an international standing thanks to his dynamism and his ability to combine emerging forensic knowledge and his research work that he implemented on crime scenes and in the laboratory. Founder of the Forensic Science College at Lausanne University, he directed the college and taught classes. Having a chemistry PhD, he became one of the major references in the forensic field. He paid tribute to Bertillon's work (he worked with him for a few months, in particular, on criminal photography, criminal anthropometry, and on the 'spoken portrait'), and befriended Locard. Reiss became an authority in forensic science through his great capacity for work; his curiosity; and his research in chemistry, photography, and any science or technique that could be useful for criminal investigation. Reiss, who had been born in Germany, rapidly appeared as an international model to follow, and was able to acquire Swiss citizenship. In 1909, Reiss founded the college at Lausanne University. He left Switzerland in 1914 to carry out a mission for the Serbian authorities to keep track of war crimes committed by the Austrian-Hungarian army on the civilian population in Serbia. He remained in Serbia until his death in 1929.

In the USA, forensic sciences quickly became central to criminal proceedings, in part because the adversarial judicial system encouraged parties to make use of forensic sciences. In the latter part of the 1920s, Los Angeles Chief of Police August Vollmer, of the Los Angeles County Sheriff's department, developed the first United States Police crime laboratory. The FBI crime laboratory was subsequently established in 1932. Edward Oscar Heinrich (1881–1953) founded the first private laboratory at Berkeley University. He was then followed by scientist Paul Kirk, who defined forensic sciences as individualization sciences, and foreshadowed current issues in forensic sciences through his work. Kirk set up in 1937 the first academic criminalistics program in the United States at the University of California.

During those early years, which were blooming with new concepts, it is worth noting that new identification methods and fields came in and out of the area of forensic sciences, thus upsetting barely established bases. For instance, criminal anthropometry, which had recently been adopted by a large number of foreign police departments, was challenged by the new field of fingerprints. Fingerprints provided methods that were useful in two fields: the fight against recidivism and traces at crime scenes. In 1823, the Czech physiologist Jan Major Purkinje described papillary drawings and claimed they were individualized. From 1858, after having observed Bengali workers authenticating deeds with fingerprints as a substitute for their signatures, Sir Williams Herschel tested this method to identify persons. In 1880, doctor Henry Faulds published an article that suggested collecting fingerprints to identify offenders. As far back as 1891, in Argentina, Juan Vucetich created a classification system using fingerprints. That system was still used in South America and in some European countries (including Switzerland) until the coming of the computer age. In 1892, Vucetich was the first one to identify a criminal thanks to fingerprints comparison. In Europe, Sir Francis Galton set the principle that fingerprints were permanent throughout life in his book 'Fingerprints' in 1892. He also created a classification system which was improved by Edward Richard Henry, head of London police department.

After the explosion of ideas by the great forerunners at the end of the nineteenth century and at the beginning of the twentieth century, their heirs and students (such as Bayle in Paris, Mezger in Germany, Sodermann in Sweden, Bischoff in Switzerland, and so on), gathered, coordinated, completed, and developed their masters' fields of research and initiatives in forensic sciences. Through systematization of scientific methods and through academic teaching, they made forensic sciences a part of criminal proceedings for good.

Thereafter, some countries stopped allowing new research in forensic science to be used in judicial proceedings, believing the field to be mature. Great Britain and France were affected by this attitude in the 1970s and 1980s. This shortcoming was highlighted by some criminal cases where confession of the culprit was systematically sought, therefore making criminal proceedings stagnate and casting aside scientific progress. It led to dropping the scientific movement which had favored the creation and development of forensic sciences. At the end of the 1980s, the realization of this setback enabled those countries to go back to an international scientific and legal standard, according to which physical evidence is collected and processed before being used as evidence in a court of law. Since the 1990s, confession is no longer the greatest kind of criminal evidence. Forensic sciences have become the scientific benchmark that legal systems cannot do without and that stands next to, if not ahead of, other kinds of criminal evidence in priority.

At the end of the twentieth and beginning of the twenty-first centuries, information technologies joined the area of forensic sciences. Criminalistics already included fingerprints, ballistics, toxicology, arson and explosives investigations, documents and handwriting analyses, microanalysis, traffic accidentology, anthropology, entomology, and so on. The field continued to expand as new forensic fields of identification, such as DNA technology, new tools that managed evidence, such as

Automated Fingerprint Identification System (AFIS), and new means of criminality, such as cybercrime, became available.

Evolving from classical serology, DNA profiling could be considered the modern-day technique revolutionizing personal identification in forensic science. In the mid-1980s, Sir Alex Jeffreys developed the techniques allowing the profile analysis of DNA. After publishing his achievements in *Nature* in 1985, Jeffreys was subsequently called upon to apply his techniques to solve the first crime in 1986. In combination with the British Home Office Forensic Science Service, his DNA profiling techniques were used to identify Colin Pitchfork as the murderer of Dawn Ashworth and Lynda Mann in Leicestershire, England. Cetus Corporation furthered the developments of DNA profiling and molecular biology techniques in personal identification during the rest of the 1980s with the development of the polymerase chain reaction (PCR). With PCR technology applied to short tandem repeats (STRs), it became possible to generate DNA profiles from tiny stains, minute amount of DNA, or fragmented DNA where longer variable number tandem repeats (VNTRs) failed to give any informative data.

Although STR analysis together with PCR amplification enabled forensic laboratories to increase sensitivity of the method and, therefore, to obtain complete DNA profiles from low DNA templates, the problem of DNA degradation of numerous crime scene samples, leading to inconclusive results, had to be solved. During 1996, the FBI DNA Analysis Unit began using mitochondrial DNA. In 2003, STR primers were redesigned to generate shorter amplicons. This approach, named 'mini-STR,' significantly improved the success rate for poor-quality samples. Nowadays 9-plex mini-STR amplification kits are on the market, and mini-STRs are implemented in various standard 15-plex STR amplification kits. These types of analyses can be applied to compromised biological samples and samples with low quantity of nuclear DNA such as hair, old bones, or teeth, allowing the examination of evidence that may not have been suitable for comparison before the development of these techniques.

While it is admitted that DNA profiling is a powerful tool for human identity testing, it is also very limited since a profile itself – in the absence of reference – provides no information to investigators with regard to the identity of the suspect. This is the reason why, in the middle of the 1990s, national DNA databases were created, first in Europe and in the United States, and later throughout the world. These DNA databases are very useful for linking serial crimes and unsolved cases with repeat offenders. In 2005, the Prüm treaty was signed up by seven European countries. This European formal decision was made to facilitate and encourage automatic exchange of DNA profiles between Member states in order to fight better against cross-border crimes. More recently, forensic scientists started to use DNA databases as an intelligence tool with the aim of finding relatives of unidentified offenders. Questions now arise on the forensic coding part of DNA, which could give phenotypes of offenders. Although this may raise some ethical and social issues, clearly DNA databases have revolutionized forensic science.

Digital evidence covers a wide range of media: optical, magnetic, and electronic, as well as several kinds of

heterogeneous data types (audio, video, desktop applications, and proprietary format), which can make a sum of very different short stories out of the whole history of digital evidence. More globally, one common story could be the research for data information in digital evidence. Beginning in the 1970s, when the viruses were discovered on Arpanet, researchers studied these programs' functionalities and tried to discover their authors. This was not necessarily very difficult because, in most of the cases, the authors identified themselves in their program or claimed authorship for fame. Although it was first easy to analyze digital information, this work quickly became complicated with the expansion and availability of the Internet, personal computers, multiple versions of operating systems, and the explosion of data storage capacity. Fortunately, at the same time, analysis tools enabling tasks automation – such as Encase, FTK, and XWays Forensics – were developing at a similar rate. These programs retrieve information and quickly analyze huge amounts of diverse information. Today, digital evidence encompasses Internet browsing history, contents of e-mail, instant messaging records, deleted data, encrypted data, and so forth. Digital evidence can be found on personal computers, mobile phones, global positioning system (GPS) devices, smart (chip-based) cards, embedded systems, identity cards, and so forth.

Throughout the world, there are now significant pressures on all forensic laboratories to implement quality management systems, and the concept of crime laboratory accreditation has gained wide acceptance in the forensic community. Accreditation is a process through which an organization becomes formally recognized to perform specific services. The laboratory seeking accreditation has to establish a structure with aims/goals, a management system, and technical facilities. All of this information is then documented in a laboratory internal quality manual. To date, there are two main accrediting bodies through which forensic laboratories are accredited around the world: The American Society of Crime Laboratory Directors/Laboratory Accreditation Board Legacy program, and the International Organization for Standardization/International Electrotechnical Commission standard 17025, which was designed for laboratories that perform testing and calibration. These national institutions are independent and duly authorized. The accreditation process is composed of three stages: the organization prepares for accreditation, then obtains it, and finally maintains it. Although the exact process varies based on the accrediting body, each organization seeking accreditation must undergo a thorough assessment conducted by a team of experts. During this assessment, the laboratory procedures and facilities are reviewed and checked against written protocols to determine compliance and non-compliance. Crime laboratory accreditation presents several advantages and drawbacks, and is an important part of creating and maintaining a comprehensive quality system. In Europe, ENFSI (European Network of Forensic Sciences) created in 1992 encourages laboratories to comply with best practice and international standards for quality and competence assurance.

Forensic science continues to be supplemented by new fields and new tools, and is still proving its vitality and relevance. After laying down the great principles, consolidating scientific methods, and undertaking constant research to develop new techniques and new capabilities, researchers in

forensic science have proved that the field is still growing and maturing. Since 1993, the US Daubert decision has laid down the principle where, before admitting expert testimony, judges have to ensure that the testimony will be reliable, that the expert has sufficient scientific knowledge, and that the expert's methods were appropriately applied to the facts at hand. Interpretation of evidence is now more questioned and appreciated by both scientists and lawyers. As a consequence, a new perspective promoting discussion on the reliability of scientific examination has developed. Far from questioning the sciences on which the examinations are based, the Bayesian probabilistic approach must help both sides in a criminal trial to better understand the value of the evidence presented by the opposing side. Paradoxically and ironically, this current evaluation phase relies on the brilliant demonstration carried out by the scientists Henri Poincaré, Gaston Darboux, and Paul Appell during the appeal hearing held in the Dreyfus case. From 1963, Paul L. Kirk has pointed out the weaknesses of evidence resulting from clues and has suggested solutions to assess the validity of evidence using the implementation of strong statistical bases to assess the evidence reliability.

Although these developments could be said to call forensic science into question, these developments are actually the beneficial result of the evolution of forensic science: they secure the chain of evidence from the crime scene to the trial. The current priorities for forensic science are the application of quality assurance standards in the chain of custody, from sampling procedures to examinations; the need to supervise laboratories, the knowledge of experts and crime scene investigators; and an understanding of how hypotheses should be formulated from the facts of the case.

Forensic science developed from a very pragmatic point of view. First, there was a need to identify persistent offenders. Second, there was a need to apply technical procedures to criminal investigations and implement the lessons learned. Third, protocols and scientific methods were applied to the chain of custody, from sampling procedures through examinations. Presently, a control phase has been implemented to ensure that results are accurate. By measuring uncertainty and using a fundamental scientific review approach, to give maturity to forensic science turn out to be the next perspective that could also participate to a better understanding of the science on its own. This will give forensic science a fair role in trials in compliance with the Justice principles including equality of opportunity.

Glossary

Abduction Syllogism in which one premise is certain whereas the other one is only probable, generally presented as the best explanation to the former. Hence, abduction is a type of reasoning in which we know the law and the effect, and we attempt to infer the cause.

Deduction Process of reasoning which moves from the general to the specific, and in which a conclusion follows necessarily from the stated premises. Hence, deduction is a type of reasoning in which, knowing the cause and the law, we infer the effect.

Forensic intelligence Understanding on how traces can be collected from the scene, processed, and interpreted within an holistic intelligence-led policing strategy.

Heuristic Process of reasoning by rules that are only loosely defined, generally by trial and error.

Holistic Emphasizing the importance of the whole and the interdependence of its parts.

Induction Process of deriving general principles from particular facts or instances, i.e., of reasoning that moves from the specific to the general. Hence, induction is a type of reasoning in which, knowing the cause and the effect (or a series of causes and effects), we attempt to infer the law by which the effects follow the cause.

Linkage blindness Organizational or investigative failure to recognize a common pattern shared on different cases.

Science The intellectual and practical activity encompassing the systematic study of the structure and behavior of the physical and natural world through observation and experiment. It is also defined as a systematically organized body of knowledge on a particular subject.

Given that it identifies and collects objects at crime scenes and then treats them as evidence, forensic science could appear at first glance to be only a pragmatic set of various disciplines, with practitioners adapting and developing tools and technologies to help the triers of fact (juries or judges) interpret information gained from the people, places, and things involved in a crime. The view could be – and has been – held that forensic science has no philosophic or fundamental unity and is merely the application of knowledge generated by other sciences. Indeed, many working forensic scientists regard themselves mainly as chemists, biologists, scientists, or technicians, and rarely as practitioners of a homogeneous body of knowledge with common fundamental principles.

Even the 2009 National Academy of Sciences National Research Council Report failed to recognize such a concept, certainly blurred by a semantic gap in the terminology itself of field practitioners, who confuse words like ‘forensic science(s),’ ‘criminalistic(s),’ ‘criminology,’ ‘technical police,’ ‘scientific police,’ and so on, and generally restrict the scientific debate on analytical techniques and methods. An independent definition of forensic science, apart from its legal aspects, would support its scientific status and return the expert to his domain as scientist and interpreter of his analyses and results to assist the lay person.

What Is Forensic Science?

In its broadest sense, forensic science describes the utility of the sciences as they pertain to legal matters, to include many disciplines, such as chemistry, biology, pathology, anthropology, toxicology, and engineering, among others. (‘Forensic’ comes from the Latin root *forum*, the central place of the city where disputes and debates were made public to be solved,

hence, defining the law of the city. Forensic generally means of or applied to the law.) The word ‘criminalistics’ was adopted to describe the discipline directed toward the “recognition, identification, individualization, and evaluation of physical evidence by application of the natural sciences to law-science matters.” (‘Kriminalistik’ was coined in the late nineteenth century by Hans Gross, a researcher in criminal law and procedure to define his methodology of classifying investigative, tactical, and evidential information to be learned by magistrates at law schools to solve crimes and help convict criminals.) In the scheme as it currently stands, criminalistics is part of forensic science; the word is a regionalism and is not universally applied as defined. Difficulties in differentiating the concepts certainly invited the definition of criminalistics as the ‘science of individualization,’ isolating this specific epistemologically problematic core from the other scientific disciplines. Individualization, the concept of determining the sole source of an item, enthroned a linear process – identification or classification on to individualization – losing sight of the holistic, variable contribution of all types of evidence. Assessing the circumstances surrounding a crime, where the challenge is to integrate and organize the data in order to reconstruct a case or propose alternative propositions for events under examination, requires multiple types of evidence, some of which may be quite nuanced in their interpretation. This is also true in the use of so-called forensic intelligence, which feeds investigative, police, or security needs, where one of the main reasons for failures is linkage blindness. Nevertheless, it seems that the essence of the forensic daily practice is hardly captured within the present definitions of both terms.

Forensic science reconstructs – in the broadest sense – past criminal events through the analysis of the physical remnants of those activities (evidence); the results of those analyses and their expert interpretation establish relationships between

people, places, and objects relevant to those events. It produces these results and interpretations through logical inferences, induction, abduction, and deduction, all of which frame the hypothetico-deductive method; investigative heuristics also play a role. Translating scientific information into legal information is a particular domain of forensic science; other sciences must (or at least should) communicate their findings to the public, but forensic science is often required by law to communicate their findings to public courts. Indeed, as the Daubert Hearing stated, “[s]cientific conclusions are subject to perpetual revision as law must resolve disputes finally and quickly.” This doubly difficult requirement of communicating to the public and to the law necessitates that forensic scientists should be better communicators of their work and their results. Scientific inferences are not necessarily legal proofs, and the forensic scientist must recognize that legal decisions based, in part, on their scientific work may not accord with their expert knowledge. Moreover, scientists must think in probabilities to explain evidence given possible causes, while jurists must deal in terms of belief beyond reasonable doubt. As Inman and Rudin state: “Because we [the scientists] provide results and information to parties who lack the expertise to independently understand their meaning and implications, it is up to us to furnish an accurate and complete interpretation of our results. If we do not do this, our conclusions are at best incomplete, at worst potentially misleading.”

The Trace as the Basic Unit of Forensic Science

The basic unit of forensic science is the trace, the physical remnant of the past criminal activity. Traces are, by their very nature, semiotic: They represent something more than merely themselves; they are signifiers or signs for the items or events that are its source. A fiber is not the sweater it came from, a fingerprint is not the fingertip, soot in the trachea is not the victim choking from a fire, blood droplets are not the violence against the victim, but they all point to their origin (source and activity) to a greater or lesser degree of specificity. Thus, the trace is a type of proxy data, that is, an indicator of a related phenomenon but not the phenomenon itself. Traces come from the natural and manufactured items that surround us in our daily lives. Traces are, in essence, the raw material available at a crime scene which becomes forensic intelligence or knowledge. Everyday items and their traces become evidence through their involvement in criminal activities; the activities add meaning to their existing status as goods in the world; a fireplace poker is transformed into ‘the murder weapon’ by its use as such. The meaning added should also take into account the context of the case, the circumstances under which the criminal activities occurred, boarding the trier of fact mandate.

Traces become evidence when they are recognized, accepted as relevant (if blurred) to the past event under investigation, and collected for forensic purposes. Confusing trace, sign, and evidence can obscure the very process of trace ‘discovery,’ which lies at the root of its interpretation. Evidence begins with detection by observation, which is possible because of the available knowledge of the investigator or scientist; unrecognized traces go undiscovered and do not become evidence. When the investigator’s or scientist’s senses are extended

through instrumental sensitivity, either at the scene or in the laboratory, the amount of potential evidence considerably increased. Microscopes, alternate light sources, instrumental sensitivity, and detection limits create increases in the number of traces that can be recognized and collected. More evidence, and more evidence types, inevitably led to increases in the complexity not only of the search for traces but also to their interpretation. Feeding back into this system is the awareness of new (micro)traces that changed the search methods at scenes and in laboratories, with yet more evidence being potentially available.

Traces are ancillary to their originating process; they are a by-product of the source activity, an accidental vestige of their criminal creation. To be useful in the determination of associations, traces whose ultimate sources are unknown must be compared to samples from a known source. Comparison is the very heart of the forensic science process; the method is essentially a diagnostic one, beginning with Georges Cuvier, and is employed by many science practitioners, including medical professionals. (Including, interestingly, Arthur Conan Doyle, a medical doctor and author, whose Sherlock Holmes character references Cuvier’s method in *The Five Orange Pips*.) Questioned traces, or items, may have a provenance (a known location at the time of their discovery) but this is not their originating source; a few examples may help:

Trace (questioned)	Source (known)
Fiber on victim	Sweater
Gunshot residue	Ammunition discharge
Blood droplet	Body
Tool marks in door jamb	Pry bar used to open door
Shoeprint in soil	Shoe from suspect
Fingerprint on glass	Finger from suspect

The collection of properly representative known samples is crucial to accurate forensic analyses and comparisons. Known samples can be selected through a variety of legitimate schemes, including random, portion, and judgment, and must be selected with great care. Thus, traces are accidental and known samples are intentional.

Some of the consequences of what has been discussed so far induce the capacities and limitations of a forensic investigation based on trace analysis. A micro- to nano-level existence allows forensic scientists to plan physical and chemical characteristics in their identifications and comparisons with other similar data. This allows forensic science to be as methodologically flexible as its objects of study require. Because time is asymmetric and each criminal action is unique, the forensic investigation and analysis in any one case is wedded, to a certain degree, to that case with no ambition to issue general laws about that event (“In all instances of John Davis being physically assaulted with a baseball bat . . .”). Inferences must be drawn with explicit uncertainty statements; the inferences should be revised when new data affect the traces’ relevancy. Therefore, the search for traces is a recursive heuristic process taking into account the environment of the case at hand, appealing to the imagination, expertise, and competency of the investigator or scientist to propose explicative hypotheses.

Two Native Principles

With this framework, two principles can be thought of as the main native principles that support and frame philosophically forensic science. In this context, principles are understood as universal theoretical statements settled at the beginning of a deduction, which cannot be deduced from any other statement in the considered system, and give coherence to the area of study. They provide the grounds from which other truths can be derived and define a paradigm, that is, a general epistemological viewpoint, a new concept to see the natural world, issued from an empiricist corroborated tradition, accepted by the community of practitioners in the field. Ultimately, this paradigm can even pilot the perception itself.

Although similar but nonequivalent versions are used in other disciplines, Locard's exchange principle exists as the central tenant of forensic science. The principle that bears his name was never uttered as such by Locard, but its universal statement of 'every contact leaves a trace' stands as a universally accepted short-hand phrasing. Locard's principle embraces all forms of contact, from biological to chemical to physical and even digital traces, and extends the usual perception of forensic science beyond dealing only with physical vestiges.

One of its corollaries is that trace deposition is continual and not reversible. Increases in the number of contacts, the types of evidence involved, and cross-transfers (A-B and B-A) also increase the complexity of determining the relevance of traces in short duration and temporally close actions.

Even the potentially fallacious rubric of 'absence of evidence is not evidence of absence' leads to extended discussions on the very nature of proof, or provable, that aims to be definitive, notwithstanding the explanations for the practical aspects of the concept (lack of sensitivity, obscuring of the relevant traces, human weakness, actual absence, etc.). Applying Locard's principle needs to address three levels. First, the physical level, which deals with ease of transfer, retention, persistence, and affinity of materials, which could better support the exchange of traces from one source to another. Second is the situational or contextual level, which is the knowledge of circumstances and environments surrounding criminal events and sets the matrix for detection, identification, and proximate significance of any evidence. Third, the intelligence level, which covers the knowledge about criminal behavior in single events or series, specific problems related to current trends in criminal behavior, and communication between relevant entities (police, scientists, attorneys, etc.); these components help the investigator in the field to focus on more meaningful traces that might otherwise go undetected.

The second, and more debated, principle is Kirk's individuality principle; again, Kirk did not state this as such beyond saying that criminalistics is the science of individualization. In its strongest form, it posits that each object in the universe can be placed demonstratively into a set with one and only one member: Itself. It therefore asserts the universal statement, "every object in our universe is unique." Philosophers like Wittgenstein have argued that without defined rules or limits, terms such as 'the same' or 'different' are essentially meaningless. There is little question that all things are unique – two identical things can still be numerically differentiated – but the

core question is, can they be distinguished at the resolution of detection applied? Simply saying 'all things are unique' is not useful forensically. For example, each fingerprint left by the same finger is unique, but to be useful, each print must also be able to be traced back to its source finger. Uniqueness is therefore necessary to claim individualization, but not sufficient. Thus, it is the degree of association that matters, how similar, how different these two things being compared are. Referring to Cole, "What distinguishes . . . objects is not 'uniqueness'; it is their diagnosticity: our ability to assign traces of these objects to their correct source with a certain degree of specificity under certain parameters of detection and under certain rules governing such assignments," or as Osterburg stated, "to approach [individualization] as closely as the present state of science allows." Statistics, typically, is required to accurately communicate levels of comparison that are reproducible. In fact, Kirk noted that individualization was not absolute. ("On the witness stand, the criminalist must be willing to admit that *absolute identity is impossible to establish*. . . . The inept or biased witness may readily testify to an identity, or to a type of identity, that does not actually exist. This can come about because of his confusion as to the nature of identity, his inability to evaluate the results of his observations, or because his general technical deficiencies preclude meaningful results" (Kirk, 1953; emphasis added).)

Nonnative Principles

Numerous guiding principles from other sciences apply centrally to forensic science, several of which come from geology, a cognate historical science to forensic science. That these principles come not from forensic science but from other sciences should not imply that they are somehow less important than Locard's or Kirk's notions. The first, and in many ways the most important, of the external principles is that of Uniformitarianism. The principle, proposed by James Hutton, popularized by Charles Lyell, and coined by William Whewell, states that natural phenomena do not change in scope, intensity, or effect with time. Paraphrased as 'the present is the key to the past,' the principle implies that a volcano that erupts today acts in the same way as volcanoes did 200 or 200 million years ago and, thus, allows geologists to interpret proxy data from past events through current effects. Likewise, in forensic science, bullets test fired in the laboratory today do not change in scope, intensity, or effect from bullets fired during the commission of a crime 2 days, 2 weeks, or 2 years previously. The same is true of any analysis in forensic science that requires a replication or reconstruction of processes in play during the crime's commission. Uniformitarianism offers a level of objectivity to historical sciences by posing hypotheses or relationships generally and then developing tests with respect to particular cases.

Three additional principles from geology hold as applicable to forensic science. They are as follows:

- *Superposition*: In a physical distribution, older materials are below younger materials unless a subsequent action alters this arrangement.

- *Lateral continuity*: Disassociated but similar layers can be assumed to be from the same depositional period.
- *Chronology*: It refers to the notion of absolute dates in a quantitative mode (such as '10:12 a.m.' or '1670–1702') and relative dates in a relational mode (i.e., older or younger).

These three principles are attributed to Nicolaus Steno but were also formalized and applied by William Smith. A forensic example of applying the principle of superposition would be the packing of different soils in a tire tread, the most recent being the outermost. A good case of lateral continuity would be the cross-transfer of fibers in an assault, given that the chances of independent transfer and persistence prior to the time of the incident would be improbable. An example of absolute chronology in forensic science would be the simple example of a purchase receipt from a retail store with a time/date stamp on it. Examples of relative chronology abound but could range from the *terminus post quem* of a product no longer made to something hotter or colder than it should be.

Evidence/Classification

I Freckelton, Monash University, Melbourne, VIC, Australia

© 2013 Elsevier Ltd. All rights reserved.

Introduction

Evidence comes before courts and tribunals in many different forms. Sometimes it is determined to be pertinent to issues in dispute; at other times, it is found not to be germane at all. Then it is said not to be 'relevant' in that it does not rationally bear upon an issue in contention. On some occasions, it is peripheral to the resolution of a case; on other occasions, it is central. It can constitute 'direct evidence' of a fact in dispute; it can also form part of a collection of matters that tend to indicate a conclusion advantageous to one party in the litigation and, so, it is 'circumstantial evidence.' Sometimes it is 'reliable,' although there are a number of different criteria that can be applied to evaluate reliability; sometimes it bears the hallmarks of being spurious. Sometimes it is 'hearsay,' by reason of coming from a source that cannot be made readily accountable, by reason of its being outside the purview of the court or tribunal, so it is of limited value.

Evidence in the form of 'tendency,' 'propensity,' and 'coincidence' seeks to induce an inference that there is consistency between previous acts and those charged, or between the perpetrators of such acts and the persons charged. Its admissibility and its utility as evidence depend on a number of important preconditions.

Evidence can be in the form of actual objects and so can be classified as 'physical' or 'real'; it can be in the form of a demonstration, simulation, reconstruction, or experiment that the tribunal of fact can observe ('demonstrative evidence'); and it can be in the form of words recounting things that have been done and inferences that have been drawn ('parole evidence').

Some evidence is 'lay' evidence in that it is not given by an expert about his area of expertise. Other evidence is given by persons possessed of specialized knowledge by reason of their skill, training, or experience. This is 'expert evidence.' Evidence by lay persons or experts can be given in the form of evidence of 'fact' – what a person did, heard, saw, or felt – or it may be given in the form of 'opinion' – what a person concluded by inference from data. Generally, evidence of speculation is not permitted, as it is not relevant, or, put another way, has little probative value.

Evidence that can be associated with a common source with a high degree of probability, such as matching fingerprints or handwriting, is often described as evidence exhibiting 'individual characteristics.' By contrast, evidence exhibiting 'class characteristics' is found when the evidence can be associated only with a class and not with a single source. This occurs, for instance, with the matching of samples of 'type AB' blood, unless DNA profiling is undertaken on it, a form of testing with the potential to yield high levels of individualization.

Relevant Evidence

Evidence is permitted to be adduced before courts only if it is 'relevant.' Relevance exists where the proposed evidence has a

tendency to make the existence of any fact that is of consequence to the determination of a criminal or civil action more or less probable than it would be without the evidence. Another formulation of relevant evidence is evidence that, if accepted, could rationally affect (directly or indirectly) the assessment of the probability of the existence of a fact in issue in the proceeding.

The distinction between relevant and irrelevant evidence is fundamental to the use to which evidence in any court case can be put. The distinction determines its admissibility and also its probative value. For this purpose, 'probative value' can be regarded as the extent to which the evidence could rationally affect the assessment of the probability of the existence of a fact in issue. Relevance is context dependent and so judges' findings about relevance are of minimal significance in terms of establishing precedents. However, a determination that evidence is not relevant, for instance, because it does not constitute evidence that could assist the trier of fact in making a particular finding, is important as it results in the removal of such information from the material that goes before the trier of fact. Evidence determined by a judge as not relevant is inadmissible.

Direct and Circumstantial Evidence

Evidence that tends to prove facts that must be proved in a case, for instance, in a criminal prosecution, can be of two kinds: 'direct' and 'circumstantial.' A litigant on occasion can adduce evidence which, if accepted, would prove a fact in issue without the need for any inference to be drawn from one fact to another. This is 'direct evidence.' If the question is whether a person is dead and the person's dead body is produced, that is direct proof of death. Where the court employs its own senses to evaluate such evidence, it is 'direct real evidence'; where the court also has cause to depend on its assessment of the veracity of a witness, it is 'direct testimonial evidence.'

By contrast, if evidence is adduced that the person suspected of being deceased disappeared mysteriously at the seaside 2 years previously after leaving a suicide note together with detailed arrangements for the resolution of his personal affairs, this constitutes 'circumstantial' or 'presumptive' evidence of his death. Lord Chancellor Cairns in *Belhaven and Stanton Peerage* (1875) 1 App Cas 278 at 279 summed up the functioning of circumstantial evidence well: "You may have a ray of light so feeble that by itself it will do little to elucidate a dark corner. But on the other hand, you will have a number of rays, each of them insufficient, but all converging and brought to bear upon the same point, and when united, producing a body of illumination which will clear away the darkness which you are endeavouring to dispel."

Although, in general, direct evidence is more reliable than circumstantial evidence, direct evidence is subject to a range of factors that can reduce its reliability, including mendacity of witnesses, and the potential for perceptual and interpretative

errors. However, the stuff of ordinary human experience, as well as of forensic evaluation, is the drawing of inferences from data in order to assess the likelihood of hypotheses. Circumstantial evidence in some contexts can therefore have considerable utility and reliability for the fact-finding process. In a criminal trial, a key issue is often whether circumstantial evidence is such as to preclude another hypothesis consistent with innocence.

Real Evidence

A fact may be proved by real evidence, cognizable by the sense of a court and not reported through the testimony of a witness. It can take many forms and is often received if of sufficient relevance and reliability. Thus, insanity may be proved by demonstration of derangement on the part of the accused; pregnancy can be proved by the appearance of an appropriately swollen belly; the fact that a child is under the age of 16 may be proved by how the child looks; the appearance of a person may be evidence of his or her nationality. In an old murder case, a court was able to conclude by inspection of the positions of the death wound and of the hole in the waistcoat of the deceased that “the wound given by the pistol under the right pap could no way happen by any position of the pistol in the bosom of the deceased, by the pistol going off by itself” (*R v. Reason* (1722) 16 How St Tr 42).

One form of real evidence is documentary evidence in which documents are tendered to the court as both proof of their existence and on occasions of what is written within them.

A further category of real evidence is the conduct of scientific or practical experiments in the presence of the jury. However, evidence of such matters is often circumscribed by trial judges lest it should arouse undue prejudice in the minds of jurors, such as the sight of particularly gruesome or distressing human or other remains. The admissibility of real evidence is also limited by reference to the extent to which items such as photographs accurately represent the facts, are fair and lack a propensity to mislead, and can be verified on oath by a person capable of doing so.

Jurors are also often cautioned against viewing themselves as experts in interpreting DNA autoradiographs, comparing tool marks, or evaluating similarities in handwriting or fingerprints. The line they are permitted to tread is a thin (and unclear) one, with their being entitled to examine exhibits themselves and draw their own inferences so long as they do not substitute their own judgments for those of expert evidence before them.

A category of real evidence is demonstrative evidence, whose purpose is to explain or illustrate. Computer-generated reenactments of matters such as aeroplane or motor vehicle collisions, or of failures of equipment or even of criminal assaults, are examples of such evidence. In general, an adequate foundation must be laid to establish both the authenticity of such evidence and its relevance. This is done in relation to reenactment evidence by showing that the underlying data are accurate; proving that the process by which the data were entered into the computer provides reasonable assurance that error was avoided; and demonstrating that tests were used to maintain the accuracy and reliability of the relevant hardware and software. In addition, in many jurisdictions it must be shown

that such evidence is more probative than it is prejudicial before it is admitted. An issue in this regard is often the accuracy of the data entered, as well as whether they could be interpreted differently. This is especially so in light of the potential for such evidence to be visually compelling and, therefore, in some circumstances, misleading or unduly prejudicial.

Parole Evidence

A substantial percentage of evidence adduced in the courts is ‘parole’ or oral evidence in the form of testimony. It is often called ‘testimonial evidence.’ Such evidence is generally given on oath and from memory, save where the witness is permitted to refer to notes or other documents. This is sometimes permitted to refresh a witness’ memory. The ‘parole evidence rule’ precluded oral evidence once an agreement had been reduced to writing, about what passed between the parties either before or after a written instrument (such as a contract) was created so as to subtract from, add to, or vary what was in the written document. However, it is subject to many qualifications in all jurisdictions.

Oral testimony is the mainstay of evidence in the Anglo-American tradition, as well as some Continental systems, such as the French, allowing decision makers to observe the demeanor and presentation of witnesses and thereby to gauge their credibility and veracity. Social science research has demonstrated that such evaluations can be flawed by reason of false assumptions and attributions. However, findings as to credibility are the preserve of the trier of fact and are amenable to appeal only to a limited extent.

Class and Individual Evidence

If it is shown that there is a match between an evidentiary exhibit found at the scene of a crime and an exhibit found in the possession of a person accused of the crime, the question then arises as to the significance of such a match. It arises in the context of many forms of matches, for example, fingerprints, DNA profiles, glass-refractive indexes, paint spicules, hairs, fibers, and shoe impressions. Some evidence possesses highly identifying features. It is termed evidence that possesses ‘individual characteristics.’ Examples include DNA profiling evidence, together with dactylography or fingerprinting evidence, and a range of forms of comparison evidence, such as toolmark, handwriting, tire or footwear impression evidence.

In general terms, the value of a piece of individual evidence is inversely proportional to the chance of false association. This chance depends on the number of comparisons which are attempted – usually against data within a pertinent database. The larger a database, the more significant a match becomes and the greater the potential for contrast between individual evidence and evidence relating to class.

Thus, evidence that establishes that an accused person had soil of a certain kind on his/her shoes and that the deceased was murdered in an area where that soil is to be found may be admissible against the accused. It is evidence that cannot uniquely identify an accused, so it can be said to possess ‘class characteristics.’ It may, nonetheless, constitute an

important part of the evidence against him/her. However, for the trier of fact to evaluate the probative value of such evidence, and for the trial judge to determine whether such evidence is more probative than it is prejudicial, it is necessary for evidence to be adduced about a range of factors that would enable the trier to evaluate the significance of such a 'match.' Included among these is the ubiquity of such soil within the relevant geographical area, thereby enabling the trier of fact to calculate how likely it is that a person with no involvement in the homicide would have such soil samples on his/her shoes. The role of relevant databases to enable evaluation of the significance of particular results, including in a statistical sense, may be significant. This may result in statistical evidence, which is classified as founded on Bayesian analysis and not permitted in some courts (*R v T* [2010] EWCA (Crim) 2439).

Reliable Evidence

Fact finders need evidence on which they can place reliance, evidence that is sound and in which trust can be reposed in determining whether an assertion in a civil or criminal case is established to the necessary degree of proof. In some jurisdictions, reliability of expert evidence is a precondition to its being admitted. This has shone light on the meaning of 'reliability' as a forensic concept.

In most jurisdictions, evidence can be excluded, at least in criminal cases, where it is accounted as more prejudicial than probative. Reliability is a factor in determining probative value.

In the United States, Canada, New Zealand, and, to some degree, in Australia, reliability is a determinant of the admissibility of expert evidence. In England it is not, although in 2011 the Law Commission recommended that consideration be given to such a change. In the United States, the influential Supreme Court decision of *Daubert versus Merrell Dow Pharmaceuticals*, 125 L Ed (2d) 469; 113 S Ct 2786 (1993) prescribed four (non-exhaustive) indicia of reliability: (1) whether scientific evidence can be or has been tested, namely its falsifiability, refutability, or testability; (2) whether the theory or technique has been subjected to peer review and publication as a means of increasing the likelihood that substantive flaws in methodology will be detected; (3) the known or potential rate of error and the existence and maintenance of standards controlling the technique's operation; and (4) whether a technique has gained general acceptance within the scientific community. The test, therefore, evaluates reliability of opinion evidence by a combination of scientific analysis and deference to the views of its legitimacy within the relevant intellectual marketplace. In other jurisdictions, extensive lists of indicia of reliability have been developed. They possess varying degrees of specificity in terms of the integrity required within the scientific process and the criteria for gauging it.

Hearsay Evidence

Evidence of a statement made to a witness by a person who is not called as a witness may or may not be hearsay. It is hearsay and frequently inadmissible when the object of the evidence is to

establish the truth of what is contained in the statement. It is not hearsay and tends to be admissible when it is proposed to establish by the evidence, not the truth of the statement, but no more than the fact that it was made. The constraints upon use of evidence that is hearsay arise out of the need by the courts to rely on evidence in which confidence can legitimately be reposed. If evidence is at second or third hand and is not capable of effective evaluation because of the absence of its primary source, the evidence is of its nature unreliable. Hence, the preclusion in most jurisdictions on much evidence that falls within the category of hearsay. However, the rule against hearsay evidence is subject to a number of qualifications and exceptions and, in some jurisdictions, such as some jurisdictions in Australia, it has been significantly attenuated to facilitate the provision of various forms of evidence that bear hallmarks of an acceptable level of reliability.

Tendency, Coincidence, and Propensity Evidence

'Tendency evidence' or 'propensity evidence' is evidence of conduct adduced to prove a person or institution's tendency to act in a particular way. Attempts are frequently made to adduce such evidence to invite the inference of conforming conduct. This is 'propensity reasoning.' 'Propensity evidence' often takes the form of evidence that an accused person has committed wrongful acts similar to those with which he/she is now charged. The inference is then invited that, because the accused has a propensity to commit a kind of crime of the sort charged, he/she has done so on this occasion. Such evidence can go to identification of an accused if there is evidence of an unusual criminal propensity; it may rebut a defense of accident and may constitute evidence of 'relationship,' 'association,' or 'passion.' The tests for the admissibility of tendency or propensity evidence differ from jurisdiction to jurisdiction. Such evidence is more probative, the more similar the past conduct and the charged conduct and the more unusual such conduct. However, such evidence is highly prejudicial and is often determined to be inadmissible or of little assistance because of being insufficiently helpful to the trier of fact and because it carries a high risk of leading to inappropriate modes of reasoning.

'Coincidence evidence' is evidence that relies on the improbability of two or more events occurring coincidentally, that is, altogether independently of each other. The more strikingly similar the events, such as crimes, and the less common, and the more unrelated by collateral circumstances are such events, the more compelling such evidence is.

Expert and Lay Evidence

Evidence is also classified by reference to the expertise of the witness. Most witnesses are lay witnesses and not permitted to give evidence in the form of opinions, except as shorthand expressions of fact (see the section Fact and Opinion Evidence).

Some witnesses who possess specialized knowledge by reason of their skill, training, or experience are designated 'expert witnesses.' However, this is a flexible and often uncertain designation, as all experts emerge gradually in knowledge and

in status from the lay toward the expert. Such a transition is a function of a series of factors including extent of knowledge, practical exposure to an area of experience, currency of expertise, and degree of specificity of expertise. With increasing subspecialization in most disciplines, it is increasingly clear that mere possession of broad academic qualifications or membership of a learned college or society is not enough to designate a person an expert for forensic purposes. However, in most jurisdictions the provenance of expertise is not important – it is the actual possession of the pertinent expertise that matters most, not so much how it was acquired.

Fact and Opinion Evidence

The status of an expert, as against a lay witness is important in determining whether or not a witness is entitled to proffer opinions to a court. Given the potential for expert witnesses to be especially influential because of their knowledge, articulateness, and testimonial experience, the designation as expert is of consequence. In general, lay witnesses are confined to evidence of what they have done, seen, heard, and felt. They can only offer opinions that are shorthand expressions of fact, for instance that a person appeared ‘sad’ or that a vehicle was traveling ‘fast.’

The privilege of expressing opinions, of drawing inferences from facts, is that of the expert witness. However, distinguishing between facts and opinions is not always easy. As long ago as 1898, Thayer wrote that, “In a sense all testimony as to matters of fact is opinion evidence; i.e. it is a conclusion from phenomena and mental impression.” As most language embodies inferences of some kind, it is not possible wholly to distinguish statements of opinion from statements of fact. All statements are in some measure inferences from experience. Judge Learned Hand frankly accepted the realities of the arbitrariness of the dichotomy in 1926: “the line between opinion and fact is at best only one of degree, and ought to depend thoroughly upon practical considerations as, for example, the saving of time and the mentality of the witness” (Central R New Jersey vs. Monahan, 11 F 2d 212 (1926)).

The distinction between fact and opinion evidence is at its most significant in legal contexts where the expertise of a witness and so his/her entitlement to give opinion evidence are in issue. For instance, in two High Court decisions in Australia, evidence was allowed to be adduced from people with practical experience, but no academic background in studying, in the jackknifing of semitrailers, and in the handling of semiarticulated vehicles on a certain road in certain conditions (Clark vs. Ryan (1960) 103 CLR 486; Weal vs. Bottom (1966) 40 ALJR 436). They were recognized as being the

repositories of knowledge above and beyond that possessed by most lay persons. In the latter case, the Court determined that the evidence sought to be given about the tendency of semiarticulated vehicles to swing out when rounding a corner, that the tendency was more marked when the road surface was slippery, and that therefore in such circumstances especial care needed to be shown, could be described as evidence of fact and therefore able to be given by persons not formally fulfilling the legal criteria for expertise.

Although experts are permitted to give evidence of opinion, they also give evidence in the form of fact. Such evidence can be particularly important – for instance, what the patient told a forensic physician, what a crime scene expert first saw upon arrival at a scene, and what a forensic pathologist observed upon the body of a deceased. Often, it is the capacity of the trained ‘scientist’ to meticulously, methodically, and accurately record observations that furnishes evidence critical to the resolution of key issues in both civil and criminal litigation.

The Frequentist Approach to Forensic Evidence Interpretation

JM Curran, University of Auckland, Auckland, New Zealand

Glossary

Probability A quantity between 0 and 1 that represents the chance of an event occurring. Probabilities may sometimes be expressed as percentages, or as odds, without loss of information. A probability may also be used to express a degree of belief that an event will occur. Such probabilities are often referred to as 'subjective.'

Probability (density) function A probability function describes the probabilities associated with the values of a discrete random variable. When the random variable is a continuous measurement, such as time or length, then a probability density function describes the density associated with a particular outcome. Density refers to the height of the curve. For a continuous random variable, the probability of an event is given by the area under the probability density curve.

Random experiment A situation where the outcome is not known in advance. One may know what the possible

outcomes are but the exact outcome is not known until the experiment is conducted.

Random variable A variable that measures the outcome of a random experiment. One may know the range of possible values that a random variable may take on, but not the actual value until the experiment has been conducted.

Sample The word sample in the statistical sense means a set, or group, of objects or measurements taken from a larger population. In this article, sample means a set of (representative) objects taken from the crime scene source or recovered from a suspect.

Specimen The word specimen is used to avoid confusion with the word sample. A specimen in this article means a smaller part, or subsample, of some evidential source. For example, one may refer to a specimen of paint from the scene. This embodies the fact that one does not have a choice when selecting a specimen, and therefore one cannot be sure that the specimen is representative of the source.

Common questions in forensic science are 'Did this evidence come from this crime scene?' or 'Does this blood come from that man?' The answers to these questions become probabilistic when the circumstances become less than certain. Statistical inference provides the tools and the framework in which probability can be addressed. Questions like those above are often called questions of common source and have been addressed with a variety of statistical frequentist techniques. These techniques are best illustrated with an example.

Example

The following example is taken from the field of forensic glass evidence interpretation.

A window is broken during the commission of a crime. Several hours later, a suspect is apprehended. Six small fragments of glass are recovered in a search of the suspect's clothing, footwear, and headgear. Random samples of six fragments of glass are taken from the crime scene window. The glass recovered from the suspect is called the recovered (or questioned) sample (or specimen), and the glass taken from the scene is called the control sample. The refractive indices (RIs) of each fragment in each sample were determined and are given in Table 1.

In the ensuing sections, some summary statistics derived from the data in Table 1 will be useful.

Range Tests

Range tests broadly describe a class of methods that compare measurements made on evidence recovered from a suspect to the range of the control source. The range of a set of

measurements is defined at the interval from the minimum observed value to the maximum observed value. The range can be expressed as an interval, for example, or as a length given by the difference of the maximum and the minimum, for example, 0.000112. The interval definition is used in this entry.

The simplest range test compares the recovered measurements in sequence to the control sample range. If a measurement falls outside of the control range, then it is deemed not to have originated from the control source. In the glass example, the smallest recovered RI measurement (1.529049) falls below the smallest control measurement; therefore, this fragment is deemed not to have come from the scene. The minimum observed in the control sample above and the maximum observed in the control sample below are the remainder of the recovered measurements; therefore, these fragments are deemed to have come from the control source. That is, in this example, five of the six recovered fragments found on the suspect are said to have come from the crime scene. The choice of language in this example is deliberately simple to illustrate the technique rather than provide a comprehensive statement about the strength of the evidence. A weaker statement might be that the control and recovered fragments have common physical characteristics.

This type of range test is easily extended to the multivariate situation. The need for this extension arises in situations where multiple measurements are made on different attributes of the same object. For example, elemental analysis techniques are commonly used in forensic science. These techniques simultaneously measure the concentrations of a number of chemical elements in a specimen. The criterion for making a statement of common source, or of similar characteristics, is that all of the measurements made on the recovered specimen

Table 1 The RIs of a control and recovered sample of glass

Control	Recovered
1.529077	1.529049
1.529085	1.529108
1.52912	1.529118
1.529133	1.529141
1.529135	1.529146
1.529189	1.529153

Table 2 An example of a range test with elemental concentration data

	Fe	Mn	Ba	Sr	Zr	Cr
Control min.	1978	53	166	143	70	1494
Control max.	2322	62	200	169	90	1771
Recovered	2320	62	192	166	99	1766

must fall within the range observed in the control sample. An example is shown in [Table 2](#). The recovered sample measurement for zirconium (99) falls outside the range observed in the control sample; therefore, this measurement would be said not to have come from the control source.

Range tests such as those described above are very simple to carry out, and require no sophisticated computation of any sort. However, they are very susceptible to outliers. Outliers, in the statistical sense, are measurements which are considerably different from the bulk of the measurements. Outliers may arise from true measurement error, misclassification, contamination, or simply by chance.

Most statisticians do not use the range as an estimate of the spread or variability of a set of measurements in any other context than simple description. Most formal statistical procedures which require a measure of variability use the sample standard deviation. This idea motivates a set of improved range tests which are sometimes called two-sigma (2σ) or three-sigma (3σ) rules.

In the simple range test, the recovered measurements are compared to an interval defined by the minimum and maximum observed values in the control sample. A 2σ rule is used to modify the control interval to the interval defined by the control mean plus or minus twice the control standard deviation, that is, $(\bar{x}_c - 2s_c, \bar{x}_c + 2s_c)$, where $\bar{x}_c$ and s_c are the mean and standard deviation of the control sample. If a 3σ rule is used, then the interval is defined by $\bar{x}_c \pm 3s_c$. Using the summary statistics in [Table 3](#), the 2σ control interval is

$$\begin{aligned}\bar{x}_c \pm 2s_c &= (1.529077 - 2 \times 4.04 \times 10^{-5}, 1.529077 + 2 \times 4.04 \times 10^{-5}) \\ &= (1.529042, 1.529204)\end{aligned}$$

The choice of two or three is motivated by what is known in statistics as the 68-95-99.7, σ - 2σ - 3σ , or the empirical rule, which states that for normally distributed data, approximately 68% of the observations lie within one standard deviation of the mean, approximately 95% of the observations lie within two standard deviations of the mean, and approximately 99.7% of the observations lie within three standard deviation of the mean. In the forensic glass example, all of the observations lie within two standard deviations of the mean, that is, within the 2σ interval. While 2σ rules have better statistical

Table 3 Summary statistics for the control and recovered measurements

Statistic	Control	Recovered
Minimum	1.529077	1.529049
Mean ($\bar{x}$)	1.529123	1.529119
Maximum	1.529189	1.529153
Standard deviation (s)	4.04×10^{-5}	3.84×10^{-5}

properties, the sequential comparison of the recovered measurements to the control intervals has an unacceptably high false exclusion rate, where the probability of declaring at least one measurement in a set of n_r measurements to be from a different source when they are indeed from the same source is given by

$$P = 1 - (1 - \alpha)^{n_r}$$

The value of α is 0.05 or 0.003 depending on whether a 2σ or 3σ rule is being used. This issue is known as a multiple comparison problem and occurs in many situations in statistics. Several practitioners claim that false inclusions rather than false exclusions are the more serious problem. That is, if a recovered item is said to have a common source with the control measurements when it is truly from a different source, then the evidence may implicate the defendant in a crime he or she did not commit. In theory, the more different the control and recovered measurements, the lower is the chance of a false inclusion. However, in practice, small sample sizes, which are common in forensic science, can badly affect the statistical properties of all approaches. In statistical terms, such tests are said to have low power. This means they have a poor probability of detecting a true difference when one exists. Both arguments have some validity, but neither is important because the frequentist approach does not consider the evidence with respect to the alternative hypothesis.

2σ rules may be used with multivariate data. The idea is easily extended by calculating 2σ or 3σ intervals for each variable measured in the control sample. If a measurement made on the recovered sample falls outside of any of the control sample intervals, then a statement of common source is not made. The extra comparisons, incurred by the extra measurements made on each item, compound the multiple comparison problem. Theoretically, this could be overcome by calculating a confidence ellipsoid for the control which is the multivariate equivalent of the interval. However, in practice, this is almost never done.

The shortcomings of range tests may be addressed by using summary statistics on the samples, such as the sample means, rather than the individual measurements. This approach has the advantage that it is less susceptible to outliers, it is less susceptible (but not immune) to multiple comparison problems, and it uses as much information as possible from the data in a single step. Such approaches usually fall into the framework of formal statistical hypothesis tests.

Formal Hypothesis Tests

The frequentist hypothesis-testing framework is commonly used in the scientific literature. It has been used in a number

of forensic disciplines to statistically address the issue of common source. This approach typically revolves around the comparison of the two sample means with respect to the observed variation in the samples.

However, most statistical hypothesis tests follow the same general steps:

1. Ask a question.
2. Formulate your question statistically – that is, find a statistic you think might answer your question.
3. Propose a null hypothesis.
4. Propose an alternative hypothesis.
5. Calculate your test statistic.
6. Calculate the P -value.
7. Interpret the P -value.

These steps use terms which need a brief definition. The null hypothesis is generally the hypothesis of no difference or no change. It means that any difference or change could easily be explained by random chance alone. It is a hypothesis that represents the statement “these measurements are (statistically) indistinguishable” or “these measurements come from the same source.” It is important to note that the second statement is not accurately reflected by the null hypothesis. The alternative hypothesis, although not formally included in the computation, is the hypothesis of difference or change. The test statistic is a summary number that may be calculated from the observed data. The P -value is defined in words as ‘the probability of observing a test statistic as large as, or larger than, the one observed if the null hypothesis is true.’ If X is any test statistic and X_0 is the value of an observed statistic in a particular case, then the P -value can be written statistically as

$$P = \Pr(X \geq X_0 | H_0 \text{ true})$$

If the P -value is small, then the correct interpretation is that the test statistic is unlikely to have occurred by random chance alone if the null hypothesis is true. In this situation, it is common to say that “the null hypothesis is rejected.” If the P -value is small, it is incorrect to assume that the result would be more likely if the alternative hypothesis were true. It is incorrect to make this assumption because no part of the calculation makes any reference to the alternative hypothesis, and, therefore, the result might be equally unlikely under the alternative hypothesis. If the P -value is large, then the correct interpretation is that the test statistic is likely to have occurred by random chance alone if the null hypothesis were true. Again, any interpretation which then infers that the result is unlikely under the alternative hypothesis is incorrect. The P -value is not the probability that the null hypothesis is true.

Significance Levels and Small or Big Values

The definition of what constitutes a small or large value is arbitrary, but is related to the acceptable risk of rejecting the null hypothesis when it really is true. This type of mistake is called a type I error. In practice, if the P -value is less than 0.05, or 0.01, then it is deemed to be small. The choice of these numbers is arbitrary, but they can be crudely interpreted as

being “less than 1 chance in 20 (or 1 chance in 100)” of making an incorrect decision (on average, if the null hypothesis is true). The caveats in the brackets in the previous sentence are quite important and are often overlooked.

The critical values 0.05, 0.01, etc. are called the significance of the test in the Neyman–Pearson orthodoxy and is usually denoted as α . The significance is, specifically, the probability of making a type I error that the user is prepared to accept. Acceptance of this probability is not dictated by the test, but by the cost associated with making an incorrect decision. In science, $\alpha=0.05$ is typically used. In legal situations, however, it may be preferable to use $\alpha \leq 0.01$. This is often viewed as complying with Blackstone’s ratio. English jurist William Blackstone said: “[It is] better that ten guilty persons escape than that one innocent suffer,” although if $\alpha=0.01$, then the ratio is 100:1 rather than Blackstone’s 10:1. Decreasing the value of α , however, is not without consequence. The smaller the value of α , the harder it becomes to reject the null hypothesis when it is false or, equivalently, to detect a difference when one truly exists. That is, the significance of a test α has a complementary relationship with the probability of making a type II error, β . β is the probability of a false acceptance, or the probability of deciding that the null hypothesis is true when in fact the alternative is true. The quantity $1-\beta$ is called the power of a test. As α decreases, β increases and, correspondingly, the power of the test is reduced.

The significance of a test is often stated in a number of different ways. People alternatively use α , $1-\alpha$, $100 \times \alpha\%$, and $100 \times (1-\alpha)\%$. That is, statements such as “the test was significant at the 0.05, 0.95, 5%, and 95% level” all occur frequently in the scientific literature. The original Neyman–Pearson framework defined α as the significance level; however, the intention of the alternatives given above is usually understood. If a P -value is smaller than the significance level (α), then the test is often said to be significant at the α level. Correspondingly, if the P -value is greater than the significance level, then the test is said to be not significant at the α level.

Hypothesis tests are more easily understood when referring to specific tests rather than in general terms. The two-sample t -test has a long tradition in scientific literature and has been used in forensic science. It is discussed in the next section.

The Two-Sample t -Test

The two-sample t -test is often used to test the hypothesis that the control sample and the recovered sample come from distributions with the same mean and variance. The inference in this situation is that if the fragments do come from distributions with the same mean and variance, then they are indistinguishable and therefore may have a common source. This is often incorrectly interpreted as “the recovered fragments come from the crime scene.”

The two-sample t -test compares the difference in the sample means to the difference that one would expect by random variation, or chance, alone. The idea is to make a probability statement about the difference in the true, but unknown, means of the sources that the samples come from.

If the means are the same, then one can say that “the recovered sample cannot be distinguished from the control scene.”

Formally, let the n_c measurements on the control sample be denoted $x_i, i = 1, \dots, n_c$, and the n_r measurements on the recovered sample be denoted $y_j, j = 1, \dots, n_r$. The control sample is assumed to have come from a normal distribution with mean μ_c and standard deviation σ_c . Similarly, the recovered sample is assumed to have come from a normal distribution with mean μ_r and standard deviation σ_r . This is expressed as $x_i \sim N(\mu_c, \sigma_c)$ and $y_j \sim N(\mu_r, \sigma_r)$. The traditional (pooled) two-sample t -test formally tests the null hypothesis that the distribution means are the same under the explicit assumption that $\sigma_c = \sigma_r = \sigma$ (and therefore that the sample standard deviations are each an estimate of the common standard deviation σ):

$$H_0 : \mu_c = \mu_r \text{ or equivalently } H_0 : \mu_c - \mu_r = 0$$

The alternative hypothesis is that the distribution means are different:

$$H_1 : \mu_c \neq \mu_r \text{ or equivalently } H_0 : \mu_c - \mu_r \neq 0$$

To test the null hypothesis, a test statistic is compared to the distribution of values one would expect to observe if the null hypothesis is true. For the two-sample t -test, the test statistic is given by

$$T_0 = \frac{\bar{x} - \bar{y}}{\sqrt{\left(\frac{1}{n_c} + \frac{1}{n_r}\right) \frac{(n_c - 1)s_c^2 + (n_r - 1)s_r^2}{n_c + n_r - 2}}}$$

where $\bar{x}$, $\bar{y}$, s_c , and s_r are the sample means and sample standard deviations of the control and recovered samples, respectively. The significance of the test is evaluated by comparing the observed value of T_0 to the distribution of values one would observe if the null hypothesis is true, or the null distribution. For the two-sample t -test, this is Student's t -distribution and is parameterized by its degrees of freedom. The degrees of freedom, $df = n_c + n_r - 2$, reflect the sample size, and in some sense, the amount of information that is available. The comparison of the observed test statistic to the null distribution is summarized by the P -value.

For the two-sample t -test this becomes

$$P = \Pr(T \geq T_0 | H_0 \text{ true})$$

The absolute value of the test statistic is used here because it makes no difference whether the recovered mean is smaller or larger than the control mean, merely the fact that it is different. It is important to note that the equal variance assumption can be relaxed. There are occasional circumstances where this is a sensible option. This version of the t -test is known as Welch's t -test. The formula for the test statistic has a different denominator, and the formula for the degrees of freedom is much more complicated, but bounded by $\min(n_c, n_r) - 1$ and $n_c + n_r - 2$.

The pooled two-sample t -test can be illustrated using the glass example. The observed test statistic is

$$\begin{aligned} T_0 &= \frac{\bar{x} - \bar{y}}{\sqrt{\left(\frac{1}{n_c} + \frac{1}{n_r}\right) \frac{(n_c - 1)s_c^2 + (n_r - 1)s_r^2}{n_c + n_r - 2}}} \\ &= \frac{1.529123 - 1.529119}{\sqrt{\left(\frac{1}{6} + \frac{1}{6}\right) \frac{(6 - 1)(4.04 \times 10^{-5})^2 + (6 - 1)(3.84 \times 10^{-5})^2}{6 + 6 - 2}}} \\ &= \frac{4 \times 10^{-6}}{2.278 \times 10^{-5}} \\ &= 0.1756 \end{aligned}$$

H_0 , the P -value, is calculated using a t -distribution with $n_c + n_r - 2 = 6 + 6 - 2 = 10$ degrees of freedom. This is easily done in Microsoft Excel using the TDIST function, or in R using the pt function. The resulting P -value is 0.86. This is a large P -value, and ‘on average one would expect a result like this approximately 86 times in 100 by random chance alone.’ That is, this result is extremely likely to have occurred by random chance alone, hence H_0 cannot be rejected. Note that, unlike the range test, this procedure does not omit the smallest recovered RI value. This information is included in both the recovered mean and, more importantly, in the recovered standard deviation. The inclusion of this fragment will increase the recovered variability and make it (slightly) harder to reject the null hypothesis. Some practitioners are bothered by this and use range-like tests to exclude observations from the evidence evaluation. Such practice can lead to dangerously misleading conclusions if no account is taken of the omitted information.

It is not entirely necessary to calculate a P -value in this example because this test statistic can be interpreted as “the observed difference is approximately 0.18 standard deviations away from the mean when the null hypothesis is true. If the observed difference was more than 2 standard deviations away from the mean, then we would start to suspect that it was unlikely to have occurred by random chance alone. Given that 0.18 is much smaller than 2, we would intuit that the observed difference can be attributed to random variation.”

The two-sample t -test has a multivariate analog known as Hotelling's T^2 . This test has been used in forensic science, but it is relatively uncommon. It is more common to perform tests on each variable. This approach is subject to the multiple testing problems discussed earlier. Hotelling's T^2 avoids such issues, and also takes into account the potential correlations between measurements. It does, however, have large sample size requirements, which traditionally have been problematic.

Confidence Intervals

Hypothesis tests have a very rigid interpretation in that the user makes a decision to either accept or reject the null hypothesis based on the P -value. Such an approach leads to what Ken Smalldon called the ‘fall-off-the-cliff effect.’ Consider a situation where the P -value is 0.049, and the criterion for rejection is 0.05. In this case, the scientist would reject the null hypothesis. However, if the P -value were 0.051, then the scientist would accept the null hypothesis. That is, a tiny change in

the numbers leads to a complete reversal of the decision. Such logic is extremely hard to justify to the court. In some situations, an alternative is to present a confidence interval.

To form a confidence interval, the scientist must choose a confidence level. The confidence level is directly analogous to the significance level for a (two-tailed) hypothesis test. The confidence level is usually stated as a percentage of the form $100 \times (1-\alpha)\%$. For example, if $\alpha = 0.05$, then this is referred to as 95% confidence level, and the resulting interval as a 95% confidence interval. Confidence intervals also have a confidence statement attached to them. That is, the scientist may state that they are $100 \times (1-\alpha)\%$ confident that the interval contains the true value of interest. Note that this is not a statement of probability. Confidence refers to the ideas of repeated sampling or infinite populations that are the foundation of the frequentist philosophy of statistics. The confidence level refers to the random nature of the interval rather than the behavior of a specific interval.

In general, confidence intervals take the form

$$\hat{\theta} \pm z_{\alpha}^* \text{se}(\hat{\theta})$$

The quantity θ is referred to as the quantity of interest. It may be a mean, a difference in means, a proportion, a difference in proportions, an odds ratio, or even a likelihood ratio. It is not a restrictive list, and it is application-specific. The quantity $\text{se}(\hat{\theta})$ is called the standard error of the estimate. It is the estimated standard deviation of the quantity of interest. The value z_{α}^* is a multiplier chosen from an application-specific statistical distribution which reflects the confidence level. In general, the smaller the value of α , the larger the value of z_{α}^* will be. Confidence intervals for many standard situations can be found in most undergraduate statistics texts.

A confidence interval for the glass example is given here for illustration. In general, a $100 \times (1-\alpha)\%$ confidence interval for the difference in the two means is given by

$$\bar{x} - \bar{y} \pm t_{\text{df}}^* (1 - \alpha/2) \text{se}(\bar{x} - \bar{y})$$

Under the assumption that the samples come from populations with the same variance, the standard error of the difference in the means is given by

$$\text{se}(\bar{x} - \bar{y}) = \sqrt{\left(\frac{1}{n_c} + \frac{1}{n_r}\right) \frac{(n_c - 1)s_c^2 + (n_r - 1)s_r^2}{n_c + n_r - 2}}$$

which is the denominator of the test statistic in the two-sample t -test. This makes sense when one considers that the hypothesis essentially compares the observed difference to the estimated variability in the difference. This formula is considerably simpler when the assumption of equal variances is dropped:

$$\text{se}(\bar{x} - \bar{y}) = \sqrt{\frac{s_c^2}{n_c} + \frac{s_r^2}{n_r}}$$

However, the formula for the degrees of freedom, given by Welch's approximation, is more complicated (and not given here). The critical value is the $100(1-\alpha/2)$ percentile of Student's t -distribution with $n_c + n_r - 2$ degrees of freedom (assuming equal variances for both populations). This can be calculated using a handbook of statistical tables, the Microsoft Excel function TINV, or the R function qt.

Therefore, a 95% confidence interval for the glass example is given by

$$4 \times 10^{-6} \pm 2.228 \times 2.277 \times 10^{-5} \\ = (-4.7 \times 10^{-5}, 5.5 \times 10^{-5})$$

The confidence interval contains 0, which is the hypothesized difference (recall $H_0: \mu_c - \mu_r = 0$). This means that if a P -value were calculated, then it would be greater than 0.05. In general, if a $100 \times (1-\alpha)\%$ confidence interval contains the hypothesized value of interest, then the associated P -value from a hypothesis test will be greater than α (for a two-tailed test), and if the interval does not contain the hypothesized value of interest, then the P -value will be less than α (for a two-tailed test).

Controversies and Issues

There has been considerable criticism in the forensic science and legal literature over the last 30 years regarding the appropriateness of frequentist approaches to the interpretation of evidence, and the relevance of frequentist methods in legal proceedings. Such discussion would seem to be at odds with the last 100 or so years in many fields of science, where frequentist methods are on the whole the accepted standard for judging experimental success.

Most of the controversy is summarized by a statement given by Robertson and Vignaux, which says that a significant hypothesis test does not answer the question the court is interested in. The court wants to know 'how much more (or less) likely does this piece of evidence make it that the accused is guilty?' A significance test on the other hand tells the court 'what is the probability that I would observe this result (match) by chance alone?' Robertson and Vignaux succinctly called this 'the right answer to the wrong question.' Proponents of the Bayesian approach, also known as the likelihood ratio approach, or the logical approach, believe that the evidence must be evaluated with respect to at least two competing hypotheses. Such a belief is not actually at odds with the Neyman-Pearson school of hypothesis testing, but in the Bayesian approach, the alternative hypothesis explicitly enters the probability calculations.

There are also more fundamental criticisms which stem from the definitions of probability. Within the field of statistics there are two schools of inference which are known as Bayesian and frequentist. These names of these schools relate, in general, to the frequentist and Bayesian definitions of probability.

The frequentist definition of probability, as the name suggests, depends on the long-term frequency of an event.

In the frequentist approach to inference, the inference relies on the concept of either an infinite population or repeated sampling. Additionally, the parameters of a model, or values about which the scientist wishes to make an inference, are generally regarded as fixed but unknown. The data are regarded as random. This means that statements are made about the random nature of the data rather than the unknown parameters. The practical consequence of this is that it should prevent the scientist from making statements about the probability of a hypothesis being true, or about a confidence interval containing the true value with a certain probability. In practice, however, such statements are still made.

By contrast, the Bayesian definition of probability is that it is a measure of belief.

In Bayesian inference, the parameters of interest are regarded as random and unknowable and the data as fixed. In the Bayesian framework, assumptions about the unknown parameters are represented by prior probabilities or beliefs, and these are updated with additional information – the data to yield posterior probabilities. This means that a scientist using Bayesian techniques can make statements about the probability of hypotheses, or probability about credible intervals containing the true value. Credible intervals are the Bayesian equivalent of confidence intervals.

It may be of some interest that it is not completely necessary to accept the Bayesian definition of probability to use the Bayesian approach.

Glossary

Bayes' theorem Bayes' theorem is a consequence of the basic laws of probabilities and can be applied for revising beliefs about uncertain propositions in the light of new evidence. In judicial contexts, reasoning according to Bayes' theorem is used in order to examine whether particular evidence strengthens or weakens a case. More generally, Bayes' theorem provides a standard for logically correct reasoning under uncertainty.

Likelihood ratio A likelihood ratio is defined by a ratio of two conditional probabilities: the probability of the

evidence given each of two mutually exclusive and competing propositions. In forensic science applications, the likelihood ratio is used as an expression for the meaning of scientific evidence and as a measure for its probative value.

Probability Probability is a measurement device for uncertainty. In one of its most widespread interpretations, it serves the purpose of expressing an individual's personal degrees of beliefs about uncertain propositions. Probability is governed by several axiomatic laws that constitute a fundamental framework for inductive logic.

Introduction

Bruno de Finetti, a pioneering subjective probabilist, considered that the role of probability theory in inductive logic is to show how the evaluations of probabilities of future events are to be modified in the light of observed events, and that this translates, in the mathematical formulation of induction, the meaning of the phrase 'to learn from experience.' Forensic scientists, as an illustrative example, routinely face inductive reasoning when they seek to evaluate or interpret the meaning of items of scientific evidence. This directs attention to Bayes' theorem, which, in essence, formalizes induction.

In Bayesian analysis, all available information is used in order to reduce the extent of uncertainty associated with an inferential problem. As new information is obtained, it is combined with any previous information, and this forms the basis for statistical procedures. The formal mechanism used to combine new information with previously available information is generally known as Bayes' theorem. Bayes' theorem involves the use of probabilities because probability can be thought of as the coherent language of uncertainty. At any given point in time, the scientist's state of information about some uncertain event (or quantity) can be represented by a set of probabilities. When new information is obtained, these probabilities are revised in order that they may represent all the available information. The idea of 'revising' probabilities is not one that should be interpreted as a 'correction.' An updated probability is not a correction or a better evaluation of an initial probability, but solely a different probability, because it is conditioned by a new (extended) state of information.

The statistical evaluation and interpretation of evidence thus relies on a rule that relates the dependencies amongst uncertain events through conditional probabilities. This rule enables one to specify the value of evidence in the sense of the effect that evidence has on beliefs in an issue, such as the guilt or innocence of a defendant. The underlying ideas can be applied to categorical and continuous data. They can also be applied to situations in which there are no, or limited,

data but in which there are subjective opinions. They are used to ensure a logical and coherent structure to the evaluation of items of evidence.

Bayes' Rule

The Bayesian approach is named after the Reverend Thomas Bayes, a nonconformist preacher of the eighteenth century. To him is attributed an important rule that shows how uncertainty about an event, say R , can be changed by the knowledge of another event, say S :

$$\Pr(R|S) = \Pr(S|R)\Pr(R)/\Pr(S)$$

where $\Pr$ denotes probability and the bar $|$ denotes the conditioning. Thus, $\Pr(R|S)$ is the probability that R occurs, given that S has occurred. Probabilities are values between 0 and 1. The value 0 corresponds to an event that is impossible to happen, and 1 to an event that is certain to happen. Probabilities are most appropriately interpreted as subjective – in the sense of 'personal' – expressions of degrees of belief held by an individual. As such they reflect the degree of imperfection of an individual's knowledge. Such belief is graduated: as evidence accumulates, one can believe in the truth of an event more or less than before, one can believe more in the truth of a given event than in the truth of another event, etc. The fundamental principle in this interpretation is that the degrees of belief of a rational individual obey the rules of probability. Therefore, probability represents the quantified judgment of a particular individual. Because a probability is a measure of a degree of belief rather than a long-run frequency (as suggested by other interpretations of probability), it is perfectly reasonable to assign probability to an event that involves a nonrepetitive situation. This makes the interpretation of probability, based on measures of belief, particularly useful for judicial contexts.

An alternative version of the Bayes' rule is its odds form, where $\bar{R}$ denotes the complement of R so that

$\Pr(\bar{R}) = 1 - \Pr(R)$. Then the odds in favor of R are $\Pr(R)/\Pr(\bar{R})$, denoted $O(R)$ and the odds in favor of R given that S has occurred are denoted $O(R|S)$. The odds form of Bayes' rule is then:

$$O(R|S) = \frac{\Pr(S|R)}{\Pr(S|\bar{R})} \times O(R)$$

In forensic science, S , R , and $\bar{R}$ are generally replaced in the odds form of Bayes' rule by E , H_p , and H_d where E is the scientific evidence, H_p is the hypothesis proposed by the prosecution, and H_d is the hypothesis proposed by the defense. Thus, one has:

$$O(H_p|E) = \frac{\Pr(E|H_p)}{\Pr(E|H_d)} \times O(H_p)$$

The left-hand side of the equation is the odds in favor of the prosecution hypothesis after the scientific evidence has been presented. This is known as the *posterior odds*. The odds $O(H_p)$ are the prior odds (i.e., odds prior to the presentation of the evidence). The factor that converts prior odds to posterior odds is the fraction

$$\frac{\Pr(E|H_p)}{\Pr(E|H_d)}$$

known as the *Bayes' factor*. In forensic contexts, it is regularly termed 'likelihood ratio' and abbreviated by V , short for 'value.' It can take values between 0 and ∞ . A value greater than one provides support to the prosecution's hypothesis H_p and a value less than one favors the defense's hypothesis H_d . Evidence for which the value is one is neutral in that the evidence is not relevant for discriminating between the two hypotheses of interest. Note that if logarithms are used, the relationship becomes additive. This has a very pleasing intuitive interpretation of weighing evidence in the scales of justice and the logarithm of the Bayes' factor is known, after the works of the statistician I. J. Good, as the 'weight of evidence.' It is not necessary for the propositions in the terms denoted $O(R)$ and $O(R|S)$ above to be complementary; the rule still holds. Thus, the prosecution and defense hypotheses do not need to be complementary.

The probative value of scientific evidence is assessed by determining a value for the Bayes' factor. The proper task of forensic scientists is the determination of that value. The role of judge and jury will be that of assessing the prior and posterior odds. Scientists can inform recipients of expert information on how their prior odds are altered by the evidence, but scientists cannot by themselves assign a value to the prior or posterior odds. In order to assign such a value, all the other evidence in a case has to be considered.

The terms 'evaluation' and 'interpretation' are sometimes considered synonyms, but it is helpful to conceive of a distinction. 'Evaluation' is the determination of a value for the Bayes' factor. 'Interpretation' refers to the meaning attached to their value.

The Value of Evidence

The evaluation of scientific evidence may be thought of as the assessment of a comparison. This comparison is between

qualities (such as genetic traits) or results of measurements (such as refractive indices of glass fragments) of crime-related (recovered) material and of control (potential source) material. For the assessment of scientific evidence, it is widely accepted that the forensic scientist should consider at least a pair of competing hypotheses, in the context habitually denoted H_p and H_d , to illustrate their description of the fact under examination. These hypotheses are formalized representations of the framework of circumstances. Their formulation is a crucial basis for a logical approach to the evaluation of evidence. A classification developed mainly by researchers in the United Kingdom during the late 1990s, referred to as a 'hierarchy of propositions,' considers three main categories or levels. It involves the so-called 'source,' the 'activity,' and the 'crime' level.

Categorical Data and Discrete Hypotheses

Source Level Evaluation

The assessment at source level depends on analyses and measurements on the recovered (of unknown origin) and control (of known origin) samples. The value of a trace (or a stain) under source level propositions, such as 'Mr. X's pullover is the source of the recovered fibers' and 'Mr. X's pullover is not the source of the recovered fibers' (so that another clothing is the source of the trace), does not need to take account of anything other than the analytical information obtained during laboratory examination. The probability of the evidence under the first hypothesis (numerator of the Bayes' factor) is considered from a comparison between two samples (the recovered and the control) assuming they have come from the same source. The probability of the evidence under the second hypothesis (denominator of the Bayes' factor) is considered by comparison of the characteristics of the control and recovered samples in the context of a relevant population of alternative sources. The population from which the source may be thought to have come is called relevant population.

Consider a scenario in which n textile fibers have been left at the scene of the crime by the person who committed the crime. A suspect has been arrested and it is desired to establish the strength of the link between the suspect and the crime. A comparison between the results of measurements of the physical/chemical characteristics of the questioned fibers and those of a sample taken from the suspect's pullover is made by a forensic scientist. The two hypotheses of interest are H_p , the fibers recovered from the suspect's pullover, and H_d , the fibers recovered from some garment other than that of the suspect. The evidence E has two parts: y , the characteristic Γ , say, of the recovered fibers, and x , the characteristic Γ , say, of the defendant's pullover. If the recovered fibers and the defendant's pullover have different (incompatible) characteristics, then the suspect's pullover would not be investigated in further detail.

Let I denote the background information. This could include (eyewitness) evidence concerning the type of garment worn by the criminal, for example. The value of the evidence is then

$$\frac{\Pr(E|H_p, I)}{\Pr(E|H_d, I)} = \frac{\Pr(x, y|H_p, I)}{\Pr(x, y|H_d, I)} = \frac{\Pr(y|x, H_p, I)}{\Pr(y|x, H_d, I)} \times \frac{\Pr(x|H_p, I)}{\Pr(x|H_d, I)}$$

Consider two assumptions:

The characteristics of the defendant's pullover are independent of whether his pullover is the source of the recovered fibers (H_p) or not (H_d) and thus $\Pr(x|H_p, I) = \Pr(x|H_d, I)$.

If the defendant's pullover was not the source of the recovered fibers (H_d), then the evidence about the fibers at the crime scene (y) is independent of the evidence (x) about the characteristics of the defendant's pullover and thus $\Pr(y|x, H_p, I) = \Pr(y|H_d, I)$.

Hence

$$V = \frac{\Pr(y|x, H_p, I)}{\Pr(y|H_d, I)}$$

The scientist knows, in addition, from data previously collected (population studies) that fiber type Γ occurs in 100% of some relevant population, say Ψ .

Assuming that the defendant's pullover is the source of the recovered fibers, the probability that the recovered fibers are of characteristic Γ , given the defendant's pullover is the source and is of characteristic Γ , is 1. Thus, the numerator of V is 1. Alternatively, it is assumed that the suspect's pullover was not the source of the recovered fibers. The relevant population is deemed to be Ψ . The true donor of the recovered fibers is an unknown member of Ψ . Evidence y is to the effect that the crime fibers are of characteristic Γ . This is to say that an unknown member of Ψ is Γ . The probability of this is the probability that a fiber donor drawn at random from Ψ has characteristic Γ , which is γ . Thus

$$V = \frac{1}{\gamma}$$

This value, $1/\gamma$, is the value of the evidence of the characteristics of the recovered fibers when the garment donor is a member of Ψ . Given that γ is a value between 0 and 1, the Bayes' factor is greater than 1, so the evidence is said to be a value $1/\gamma$ times more likely if the suspect's pullover was the source of the recovered fibers than if it were not. Qualitative scales have been proposed and they are intended to make it easier to convey the meaning of the numerical value of the evidence. However, there is ongoing discussion about the degree to which this target has been achieved.

Activity Level Evaluation

The hierarchical level relates to an activity. It requires that the definition of the hypotheses of interest include an action. Such hypotheses could be for example, 'Mr. X sat on the car driver's seat,' and 'Mr. X never sat on the car driver's seat.' The consequence of this activity – the sitting on a driver's seat – is a contact between the driver and the seat of the car. Consequently, a transfer of material (i.e., fibers in this example) may be expected. Therefore, the scientist needs to consider more detailed information about the case under examination. It relates to the transfer and persistence of fibers on the car driver's seat. This demonstrates that activity level hypotheses cannot be addressed without a framework of circumstances.

Consider, for the sake of illustration, the following scenario. A crime has been committed during which the blood of a victim has been shed. A suspect has been arrested. A single blood stain of genotype Γ has been found on an item of the suspect's clothing. The suspect's genotype is not Γ . The victim's genotype is Γ . There are two possibilities:

T_0 : the blood stain came from some background source;

T_1 : the blood stain was transferred during the commission of the crime.

As before, there are two hypotheses to consider:

H_p : the suspect assaulted the victim;

H_d : the suspect did not assault the victim (for example, but taken to mean he is not involved in any way whatsoever with the victim).

The evidence E to be considered is that a single blood stain has been found on the suspect's clothing and that it is of genotype Γ . The information that the victim's genotype is Γ is considered as part of the relevant background information I . A general expression of the value of the evidence then is $V = \Pr(E|H_p, I) / \Pr(E|H_d, I)$.

Consider the numerator first and event T_0 initially. This supposes 'a contact' between the suspect and the victim, but no blood transfer to the suspect. This is an event with probability $\Pr(T_0|H_p, I)$. Also, a stain of genotype Γ must have been transferred by some other means, an event with probability $\Pr(B, \Gamma)$ where B refers to the event of a transfer of a stain from a source (i.e., a background source) other than the crime scene (here the victim).

Next, consider T_1 , the event of blood transfer to the suspect, an event with probability $\Pr(T_1|H_p, I)$. Given T_1, H_p and the genotype Γ of the victim, it is certain that the transferred stain is Γ . This assumes also that no blood has been transferred from a background source.

Let $t_0 = \Pr(T_0|H_p, I)$ and $t_1 = \Pr(T_1|H_p, I)$ denote the probabilities of no stain or one stain being transferred during the course of the crime. Let b_0 and b_1 , respectively, denote the probabilities that a person from the relevant population will have zero blood stains or one blood stain on clothing. Let γ denote the probability that a stain acquired innocently on the clothing of a person from the relevant population will be of genotype Γ . This probability may be different from the proportion of individuals in the general population which are of type Γ . Then $\Pr(B, \Gamma) = \gamma b_1$ and the numerator can be written as $t_0 \gamma b_1 + t_1 b_0$. This expresses that the presence of a stain of type Γ depends on the probability of there being no transfer (t_0), times there being such a stain as background ($b_1 \gamma$), plus the probability of transfer of such a stain (t_1), times the probability of there being no such stain beforehand (b_0).

Now consider the denominator where it is supposed that the suspect and the victim were not 'in contact.' The presence of the stain is then explained by chance alone. The denominator then takes the value $\Pr(B, \Gamma)$ which equals γb_1 .

In summary, the value of the evidence is thus

$$V = \frac{t_0 \gamma b_1 + t_1 b_0}{\gamma b_1}$$

Extensions to cases involving transfer in the other direction (from perpetrator to scene/victim rather than from scene/victim to perpetrator), for example, or generalizations involving n stains and k groups are available in the specialized literature on the topic.

Crime Level Evaluation

At the 'crime level,' hypotheses are closest to those of interest to the jury. A formal development of the likelihood ratio under

'crime level' hypotheses shows that two additional parameters are of interest: (1) one concerns material that may be 'relevant,' meaning that it came from the offender (it is relevant to the consideration of the suspect as a possible offender), (2) the other concerns the recognition that if the material is not relevant to the case, then it may have arrived at the scene from the suspect for innocent reasons.

Consider the following two hypotheses of interest:

H_p : the suspect is the offender;

H_d : the suspect is not the offender.

Notice the difference between these hypotheses and those of the previous sections on source or activity level. At source level, the hypotheses referred to the suspect being, or not being, the donor of the recovered trace found at the crime scene. Now, the hypotheses are stronger, because they specify the suspect as a possible offender.

In the formal development of the likelihood ratio, a link is needed between what is observed (i.e., the stain at the crime scene) and the hypotheses according to which the suspect is or is not the offender. The connection is made in two steps. The first is the consideration of a hypothesis that the crime stain came from the offender and the alternative hypothesis that the crime stain did not come from the offender. If it is assumed that the crime stain came from the offender, the second step is the consideration of a hypothesis that the crime stain came from the suspect and the alternative that the crime stain did not come from the suspect.

Developing the likelihood ratio in view of these two pairs of hypotheses introduces the concepts of (1) 'relevance probability,' usually denoted r , and (2) 'innocent acquisition probability,' usually denoted as a . The resulting expression of the value of the evidence takes the following form:

$$V = \frac{r + \gamma'(1-r)}{\gamma r[a + (1-a)\gamma'](1-r)}$$

Note the difference between two possible expressions γ and γ' of the rarity of the corresponding characteristic. In fact, γ' is the probability that the crime stain would be of a given type, if it had been left by an unknown person who was unconnected with the crime. The population of people who may have left the stain is not necessarily the same as the population from which the criminal is assumed to have come. For DNA evidence, however, it may be acceptable to assume $\gamma = \gamma'$.

Continuous Data and Discrete Hypotheses

A seminal paper in 1977 by Dennis Lindley showed how the Bayes' factor could be used to evaluate evidence given by continuous data in the form of measurements. The measurements used by Lindley by way of illustration were those of the refractive index of glass. There were two sources of variation in such measurements, the variation within a window and the variation between different windows. Lindley showed how these two sources of variation could be accounted for in a single statistic. He was also able to account for the two factors which are of importance to a forensic scientist: (1) the similarity between the recovered and control sample and (2) the typicality of any perceived similarity. When the data are in

the form of continuous measurements, the Bayes' factor is a ratio of probability density functions rather than a ratio of probabilities.

Consider a set $\mathbf{x}$ of control measurements and another set $\mathbf{y}$ of recovered measurements of a particular characteristic, such as the refractive index of glass. For this example, $\mathbf{x}$ would be a set of measurements of refractive indices on fragments of a broken window at the crime scene and $\mathbf{y}$ a set of measurements of refractive indices on fragments of glass found on a suspect. If the suspect was at the crime scene then the fragments found on him could have come from the window at the crime scene. If he was not there then the fragments have come from some other, unknown, source.

The quantitative part of the evidence concerning the glass fragments in this case can be denoted by $E = (\mathbf{x}, \mathbf{y})$. The Bayes' factor is then written as follows:

$$V = \frac{f(\mathbf{x}, \mathbf{y} | H_p, I)}{f(\mathbf{x}, \mathbf{y} | H_d, I)}$$

Bayes' theorem and the rules of conditional probability apply to probability density functions $f(\cdot)$ as well as to probabilities. The value of the evidence V of the evidence may be rewritten – following the argument presented in the section on discrete data – as

$$V = \frac{f(\mathbf{y} | \mathbf{x}, H_p, I)}{f(\mathbf{y} | H_d, I)}$$

This formulation of the expression for V shows that for the numerator the distribution of the recovered measurements, conditional on the control measurements as well as I , is considered. For the denominator, the distribution of the recovered measurements is considered over the distribution of the whole of the relevant population. The denominator is called the 'marginal distribution' of the recovered measurements in the relevant population.

In a Bayesian approach, the characteristic of interest is parameterized, for example by the mean. Denote the parameter by θ . This parameter may vary from source (window) to source (another window).

Consider the two propositions to be compared are

H_p : the recovered sample is from the same source as the control sample;

H_d : the recovered sample is from a different source than the control sample.

The measurements $\mathbf{x}$ are from a distribution with parameter θ_1 , say and the measurements $\mathbf{y}$ are from a distribution with parameter θ_2 , say. If $\mathbf{x}$ and $\mathbf{y}$ come from the same source, then $\theta_1 = \theta_2$, otherwise $\theta_1 \neq \theta_2$. In practice, the parameter θ is not known and the analysis is done with the marginal probability densities of $\mathbf{x}$ and $\mathbf{y}$. The above equation for V can be rewritten as:

$$V = \frac{\int f(\mathbf{y} | \theta) f(\mathbf{x} | \theta) \pi(\theta) d\theta}{\int f(\mathbf{x} | \theta) \pi(\theta) d\theta \int f(\mathbf{y} | \theta) \pi(\theta) d\theta}$$

For those unfamiliar with these kinds of manipulations, Bayes' theorem applied to conditional probability distributions is used to write $f(\theta | \mathbf{x})$ as $f(\mathbf{x} | \theta) \pi(\theta) / f(\mathbf{x})$. The law of total probability with integration replacing summation is

used to write $f(x)$ as $\int f(x|\theta)\pi(\theta)d\theta$. Note that $\pi(\theta)$ represents the prior distribution on the unknown parameter. Therefore, the Bayes' factor does not depend only upon the sample data. It is the ratio of two weighted likelihoods.

Often, the distributions of $(x|\theta)$ and $(y|\theta)$ are assumed to be normal, with θ representing the mean, varying from source to source, and the variance is assumed to be constant from source to source. Those assumptions can be relaxed and (a) various possibilities can be assumed for the distribution of $(x|\theta)$, $(y|\theta)$, and θ and (b) a three-level hierarchical model (variance assumed not constant) can be considered. Moreover, developments for multivariate data are also possible.

Principles of Evidence Evaluation

Three principles arise from the application of the ideas outlined so far.

First, the evaluation is meaningful only when at least one alternative hypothesis is addressed. So, the distribution of the data has to be considered under (at least) two hypotheses, typically that of the prosecution and that of the defense.

The second principle is that evaluation is based on consideration of probabilities of the evidence, given a particular issue is assumed true, $\Pr(E|H_p)$ and $\Pr(E|H_d)$.

The third principle is that the evaluation and interpretation of the evidence is carried out within a framework of circumstances. It has to be conditioned on the background information I .

The application of those principles guarantees some desiderata in the scientist's attitude in evaluating and offering evidence, such as balance, transparency, robustness, and added value. The degree to which the scientist succeeds in meeting these criteria depends crucially on the chosen inferential framework which may be judged by the criteria of flexibility and logic.

Interpretation

Continuous Data and Continuous Hypothesis

So far the outline focused on categorical (or continuous) data and discrete hypotheses, but Bayesian analysis also deals with situations involving continuous hypotheses. In particular, it may happen that scientists encounter continuous propositions. A typical instance of this is the situation where a parameter, such as a mean, needs to be estimated. As an example, suppose that a random sample, $x = (x_1, \dots, x_n)$, is available. For example, this may be the case in which a scientist is interested in blood alcohol concentration on the basis of a series of n measurements taken from a given individual arrested by traffic police.

Suppose further that the data follow a Normal distribution with unknown mean, θ , and known variance, σ^2 . Suppose also that there is some background information available so that some values of θ seem more likely a priori. Then, assuming a conjugate Normal prior distribution for the parameter of interest, that is the mean θ , having a mean μ and a variance τ^2 , it can be shown that the posterior density is still normal distributed, $N(\mu(x), \tau^2(x))$, with

$$\text{mean } \mu(x) = \frac{\frac{\sigma^2}{n}}{\frac{\sigma^2}{n} + \tau^2} \mu + \frac{\tau^2}{\frac{\sigma^2}{n} + \tau^2} \bar{x} \text{ and variance } \tau^2(x) = \frac{\frac{\sigma^2}{n} \tau^2}{\frac{\sigma^2}{n} + \tau^2}$$

The posterior mean is a weighted average of the prior mean μ and the sample mean $\bar{x}$, with weights proportional to the variances corresponding to the prior distribution and the sampling distribution. Comparable lines of reasoning can be invoked to approach situations involving unknown variances, alternative distributions and data distributions.

Pitfalls of Intuition

The Bayesian approach to the interpretation of evidence enables various errors and fallacies to be exposed. The most well-known of these are the prosecutor's and defender's fallacies. As an example, consider a crime where a blood stain is found at the scene and it is established that it has come from the criminal. Only for sake of illustration, consider that the stain has a profile which is present in only 1% of the population. It is also supposed that the size of the relevant population is 200 000. A suspect is identified by other means and his blood is found to be of the same profile as that found at the crime scene.

The prosecutor argues that, because the blood profile is present in only 1% of the population, there is only a 1% chance that the suspect is innocent. There is a 99% chance that he is guilty. The defense attorney argues that, because 1% of 200 000 is 2000, the suspect is only one person in 2000. There is a probability of 1/2000 that he is guilty. This is then used to argue that the blood group is, therefore, of little probative value and not very helpful in the case.

Consideration of the odds form of Bayes' rule explains these fallacies. Denote the blood evidence by E and let the two competing hypotheses be H_p , the suspect is guilty, and H_d , the suspect is innocent. Then the odds form of Bayes' rule is that (omitting I from notation)

$$\frac{\Pr(H_p|E)}{\Pr(H_d|E)} = \frac{\Pr(E|H_p)}{\Pr(E|H_d)} \times \frac{\Pr(H_p)}{\Pr(H_d)}$$

The Bayes' factor is $\Pr(E|H_p)/\Pr(E|H_d) = 1/0.01 = 100$. The posterior odds are increased by a factor of 100.

Consider the prosecutor's statement. It claims that the probability of guilt, after presentation of the evidence, is 0.99. In formal terms, this corresponds to $\Pr(H_p|E) = 0.99$ and, hence, $\Pr(H_d|E) = 0.01$. The posterior odds are 99, which is approximately 100. V is also 100. Thus, the prior odds are 1 and $\Pr(H_p) = \Pr(H_d) = 0.5$. For the prosecutor's fallacy to be correct the prior belief is that the suspect is just as likely to be guilty as innocent.

The defense argues that the posterior probability of guilt $\Pr(H_p|E)$ equals 1/2000 and, hence, $\Pr(H_d|E)$ equals 1999/2000. The posterior odds are 1/1999, which is approximately 1/2000. Since the posterior odds are bigger by a factor of 100 than the prior odds, the prior odds are 1/200 000, or the reciprocal of the population size. The defense is arguing that the prior belief in guilt is approximately 1/200 000. This could be expressed as a belief that the suspect is just as likely to be guilty as anyone else in the relevant population. The fallacy arises because the defense then argues that the evidence is not

relevant. However, before the evidence was led, the suspect was one of 200 000 people, after the evidence was led he is only one of 2000 people. Evidence which reduces the size of the pool of potential criminals by a factor of 100 is surely relevant.

Other errors have been identified. The 'ultimate issue error' is another name for the prosecutor's fallacy. It confuses the probability of the evidence if a defendant is innocent with the probability he is innocent, given the evidence. The ultimate issue is the issue proposed by the prosecution of which it is asking the court to find in favor. The 'source probability error' is to claim the defendant is the source of the evidence. This would place the defendant at the scene of the crime but would not, in itself, be enough to show that he was guilty. The 'probability (another match) error' consists of equating the rarity of a characteristic with the probability that another person has this characteristic. The 'numerical conversion error' equates the reciprocal of rarity of the corresponding characteristic to the number of people that have to be examined before another person with the same characteristic is found.

More generally, high values for the evidence provide strong support for the prosecution's case. They are not, however, sufficient in themselves to declare a defendant guilty. The prior odds have to be considered as well. Very high values for the evidence, when combined with very small values for prior odds, may produce small values for the posterior odds. This may be the case when the suspect has been selected as a result of a database search and when there is little or no other evidence against the suspect.

Glossary

Forensic intelligence The accurate, timely, and useful product of logically processing forensic case data for crime investigation and crime analysis purposes.

Trace The remnant of a presence or an action. Pattern, signal, or object, the 'trace' is an apparent sign, which is sometimes latent.

Introduction

Forensic science plays an ever-increasing and critical role in the justice system. It operates generally in supporting criminal and civil investigations and/or providing expert opinion and 'scientific' information to assist courts in their decisions.

Forensic intelligence encompasses and goes beyond assisting in investigations and court decisions. It does this through the interpretation of forensic case data (i.e., marks or traces of various types left behind or made by a person or his/her accessories during the commission of an unlawful act) that contribute to decision making in a variety of ways. When forensic science is integrated in policing contexts, it can operate as a silent witness helping to support strategic decisions, police operations, or crime prevention without involving a court case. For instance, forensic science frequently provides leads to investigators before a person is arrested (e.g., major crime inquiries). It can also assist in a more proactive style of policing (e.g., intelligence-led policing) and to crime analysis functions through the potential to link persons, crimes, and crime scenes. Forensic intelligence has demonstrated promising capabilities and is still developing in many directions.

Currently, within forensic science there is a debate about what role it should take and what contribution it should make. In the context of this debate, the concept of forensic intelligence has created some tensions. Some practitioners adopt the position that forensic science should be strictly justice oriented in a traditional paradigm, whereas many practitioners who work within policing environments adopt a position that broadens the role of forensic science into the security system. Both systems overlap without a clear integration. Therefore, in attempting to clarify its practical contribution, forensic science does not escape the very old debate about how justice and security are configured.

Traces as Forensic Case Data, Sign, Information, Evidence, and Intelligence

Forensic science is the study and analysis of traces. Traces can be defined as the remnant of a presence (a person or object located at a certain place at a certain time) or of an action. Whether it be a pattern, a signal, or an object, a 'trace' is an apparent sign of presence or actions. Traces can also sometimes be latent.

There are several essential characteristics of traces, which are listed below:

- A trace has a reality that exists independently of any meaning that can be attributed to it.
- It comes from the past and cannot be reproduced.
- It can be fragmentary, incomplete, imperfect (remnant).
- It is not usual within a given environment; it is the effect of an unusual activity at a place at a given time which has disrupted the usual equilibrium of the environment.
- A pertinent trace has generally been transferred unknowingly by the person who committed the action (a planted trace may be indicative of deception).
- It contains a sign which is information on its source (who, with what).
- It contains information about the action which has produced it (how, when, where, what, why).

One of the many consequences of these essential characteristics is that the trace allows the measurement of its physical, chemical, and biological elements. These measurements can be compared with other data or information, independently of any meaning. The trace becomes meaningful only after analysis when the results have been interpreted within a context; for example, when the trace is connected with an event of interest. In forensic science, an event becomes an event of interest when it breaches criminal or civil codes and other laws or rules.

Of importance is the process through which a trace, the material element, becomes an explanation of the circumstances of its presence, which affects its subsequent use. The trace becomes a sign that conveys information about what has occurred. Traces only become evidence after the court has considered the relevance of the trace to the case in order to assist the court in its decision. At this point, forensic intelligence broadens the scope of forensic science through the many other ways of interpreting traces. Here, 'evidence' generalizes to 'intelligence.' Intelligence can be defined as *the interpretation of forensic case data to support a variety of different decisions in the interconnected web of processes crossing each policing system.*

Within forensic intelligence, it is argued that any discipline interested in unlawful events where traces are generated should consider the integration of forensic case data as a primary piece of information. Can we realistically talk about violent criminal behavior without considering the physical exchanges that took place? Or of illicit drug trafficking without studying the substances in question, their manufacturing process, and their

effects on people? Or of fire and arson without considering the mechanisms of combustion? Or of counterfeiting without understanding the manufacturing processes and the marks they produce? Or of environmental problems without considering the chemical analysis of suspected specimens? From this perspective, forensic intelligence combines certain approaches in criminology with forensic science.

The potential value of forensic intelligence within contemporary policing models is clear and it can be coherently integrated into policing at strategic, operational, and/or tactical levels.

Intelligence-Led Policing

Forensic intelligence operates within police environments. There are many models of policing, all of which recognize the fluidity of information and the rigor of its treatment as critical aspects contributing to efficacy and efficiency.

One of these models is intelligence-led policing. This model promotes a systematic analysis of available information that allows decisions to be made at the strategic, operational, and/or tactical level. This type of policing, where an analytical capacity is developed and utilized, provides a mechanism for achieving a greater understanding of security challenges and addressing them in a proactive way. Crime and criminal intelligence analysis is the term given to the organization of collected data that has been collated and analyzed. This knowledge is then disseminated and becomes 'intelligence' that can be used by decision makers.

One of the key challenges is to determine how forensic case data can be processed and integrated into intelligence-led policing models. At the very least, decision making in such models can be informed by logically processed information arising from an organized memory of traces, presented in a timely and usable form according to the decision to be taken. This form of intelligence can be invaluable in making informed decisions.

Intelligence-Led Systems and Examples of Forensic Intelligence Activities

In an intelligence-led policing system, the variety of forms that forensic intelligence could take has not yet been fully explored or formalized. In order to illustrate its contributions, some components of the system and their interactions are presented in the simplified model (Figure 1).

Of importance is the overlap between criminal justice and security systems. More often than not, this overlap is not clearly defined. We now turn to describe how forensic intelligence covers four main categories or functions.

Tactical Intelligence and Investigative Leads

According to Kind, the judicial process operates in three chapters: first, the problem to find; second, the decision to charge; and last, the trial process. Each chapter has its own logic, beginning with the facts, interpreting the facts, then potentially discovering a profile of the person and of his/her activity. This leads to a structuring of information which makes the process more deductive and involves assessing the consequences if the person participated in the activity. Finally, there is the trial itself with a more general focus on justice and an interest in forensic science. The implementation of the process depends heavily on the judicial context and its procedures: competencies for making decisions are distributed in very different ways in different jurisdictions. However, whatever the organization, at many points, the interpretation and intelligence provided by forensic case data support decision making. For instance, forensic intelligence can occur in a tactical context when

- Pointing to a suspect (e.g., through a database) or a set of persons (when partial DNA is compared to a database) in order to direct the investigation;
- Eliminating persons previously of interest through DNA sweeps;

Figure 1 A very simplified and limited model showing the overlap between security and the criminal justice systems. It illustrates the central role of intelligence that should drive most functions. The particular components that are displayed are interconnected. They can partly or significantly rely upon forensic intelligence. Investigations, divided into three chapters in the judicial process, according to Kind, overlap with the policing environment. This is a source of tensions that are addressed further.

- Analyzing a substance seized on a person in order to help establish the crime (e.g., confirming an illicit substance or determining the quantity). Further, to check if the substance can be linked with other seizures that will indicate if this should be treated as a separate case or as elements of organized trafficking. In addition, presenting this information as intelligence may support a decision about detaining a person/s;
- Detecting serial offenses carried out by the same person through crime scene linking (e.g., the comparison of footmarks, DNA, and earmarks). On this basis, analyzing the series and suggesting lines of inquiry or proactive operational procedures (e.g., surveillance or decoy);
- Understanding a modus operandi through the analysis of a crime scene that can help devise a profile of the perpetrator, and subsequent lines of inquiry.

Operational Intelligence Through Sustained Crime Analysis

The sustained collection, collation, and analysis of specific forensic case data can improve many crime analysis processes and subsequently support decisions of all kinds.

One of the most elementary and systematic police tasks is to check and establish the identity of a person or persons. This frequently occurs in the street or at particular checkpoints. Many methods exist for checking identities, the most applicable depending largely on the context in which it occurs (time, availability of techniques, light). A basic operational field task in many countries is the careful examination of identity documents. Field officers carry out this task and must be informed and trained about the relevant features to check in a document. However, a variety of evolving techniques are being used by different counterfeiters to deceive document examiners. This knowledge and the real-time determination of the best method for checking documents must be systematically updated and disseminated to field officers.

For this purpose, a forensic intelligence process can be delineated. It consists of collecting fraudulent documents and observations from field officers. The documents and the observations are then collated, compared, and analyzed to extract relevant characteristics resulting from the current manufacturing processes used by criminals. How these characteristics can be detected as simply as possible is determined and eventually this knowledge is disseminated and used as intelligence for supporting decisions made when checking documents in the field.

This process can be generalized to tackle a variety of counterfeiting problems faced by authorities. The continuous analysis and monitoring of potentially counterfeited watches, drugs, and other objects and materials can benefit from the implementation of such specific forensic intelligence processes.

Forensic intelligence is not limited to this specific case; the approach can be generalized in relation to different types of crime activities or problems. High-volume crimes, violent crimes, the use of guns, and other repetitive problems such as arson and fire or even graffiti may benefit from the integration of forensic case data with other more traditional data used for this purpose (geographical information, chronologies, modus operandi). This list can be extended to include other national security themes relating to terrorism.

Currently, the management of these problems focuses on traditional sources of information and does not make use of forensic intelligence except when dealing with specific cases. These traditional methods do not take advantage of the strengths and potential value of the information obtained through forensic science. The current approach is not coherent and it misses one of the richest sources of information since repetitive crimes are more firmly linked through forensic comparisons than by other more fragile methods, such as hunches or psychological profiles. How to build the best (simple, flexible, adaptive, cost-effective, respectful to privacy, rapid, selective) architecture for the sustained analysis of crime problems is a real challenge and the basis of intensive research.

Strategic Intelligence Through the Integration and Analysis of Forensic Links

Linking crimes through forensic case data provides information on the size, the extent, and the evolution of criminal phenomena. This inductive process leads to a model that may add value to knowledge gained through other criminological studies. For instance, the systematic detection of links through illicit drug profiling provides intelligence that eventually influences strategic decisions at a political level or informs prevention programs (e.g., detecting products that pose a risk to population health, or detecting the routes used to traffic illicit substances). DNA linking creates potentially relevant information about the structure of certain forms of criminality (how repetitive), the mobility of criminals (how each criminal travels), or even about criminal careers. Nevertheless, the strategic use of forensic case data is still very rare despite its advantages; typically, policing organizations offer no rational explanations other than following routine and the lack of training and education.

Forensic Science Performance

In an intelligence-led style of policing, systematically assessing the efficiency of each forensic intelligence function is a fundamental attitude. This leads to a focus on the cost/benefit ratio of the activity depending on the objectives that relate to various strategies. In this model, performance indicators often focus on crime detection or conviction in order to perceive how forensic science contributes to the justice system. These can be valid indicators when forensic science is considered from a traditional perspective. However, forensic intelligence cannot be evaluated in this way because its added value resides in how it supports decision making in policing, not in directly solving crime.

Limits of Forensic Intelligence, and Requirements

The nature of traces limits the extent and types of inferences that can be made. Traces come from the past, and the course of time is not reversible. Singular events cannot be reproduced; they must be imagined through abduction (what are the possible or reasonable causes of the observed effects?). Moreover, traces can be fragmentary and incomplete, and their relevance uncertain. In addition, incompleteness is a characteristic of

crime scene processing: there is no established procedure guaranteeing that the material associated with the investigated activity will be found; absence of traces does not mean that no trace exists.

These considerations highlight some of the logical difficulties that go beyond techniques and methods. A number of significant consequences follow:

- Information is lost forever. Crime scene examination aims to optimize the quantity and quality of material collected. This means that crime scene examination cannot be restricted to the systematic application of standard operating procedures and techniques. It necessitates the adoption of a scientific attitude (in a broad sense) at the scene through the logical processing of what is observed.
- The types of reasoning that rely on traces are said to be 'approximate' and 'non-monotonic,' that is, each new piece of information may provoke the revision of what was inferred.
- The trace does not tell the whole history, only a part of it that may be substantial (or not) according to the problem at hand and the recovered material. It is frequently useless when used in isolation. The trace must be integrated within a framework that collates and interprets the many sources available, thereby limiting any breaks in the reasoning process that result from arbitrary inferences being made in separate disciplines.

Challenges and Tensions

These fundamental limitations explain why traditional forensic organizations experience many difficulties in dealing with intelligence issues and integration.

First, delivering forensic intelligence 'services' and evaluating their efficiency according to a formalized relationship between a client and a customer is very hard, if not an intractable task. For instance, in the course of a major inquiry, relevant operational decisions depend strongly on the case itself as well as the reasoning capacity of the team that is in charge; they cannot be defined in routine terms. An investigation calls for transversal, fluid, and hard-to-formalize reasoning that uses general forensic science and other knowledge; for example, crime analysts, behavioral scientists, pathologists, investigators, and forensic scientists are more frequently required to work in an integrated way in major inquiries nowadays. However, this is not the case in most forensic science laboratories where activities are separated according to traditional branches of the hard sciences (e.g., chemistry, biology, physics) or more modern disciplines (e.g., computer science, life sciences). This is exemplified by the influential NAS report (2009) that does not identify the richness of the information content that may be obtained through integration and formal analysis. There is a need to develop specialist support knowledge; however, it is well known that specialized (and separated) organizations privilege their own objectives according to their vertical structures. They tend to adopt a negative view of horizontal processes that involve the sharing of knowledge across agencies, in part due to concerns related to accountability; at the very least, they do not prioritize such processes. Specialist organizations

have therefore had dramatic and negative effects on the development of forensic intelligence.

The previous argument should lead to a reformulation of the process from a policing perspective. A change of culture is needed in many policing organizations for a better integration of forensic case data. Crime analysis units also need to be aware of the benefits of integrating forensic intelligence.

Finally, forensic policy and its efficiency cannot be entirely evaluated according to justice concerns. A better general question is: How does forensic science contribute to crime reduction? Of course, this is a complex question that is difficult to address through the application of valid experimental methods. However, other less ambitious but related questions can be answered. For instance, what is the performance of forensic case data (and their combination) in linking crimes and thus supporting crime analysis functions? What is the quality and quantity of traces collected, and what do they contribute to intelligence processes? And how can forensic science boost other activities? However, the assessment framework for addressing these questions is still in its infancy.

The integrative form of problem solving inherent in forensic intelligence is useful for examining both specific cases and the evolution of criminality more generally. Importantly, however, it is at odds with recent propositions that call for more standard operating procedures, and the separation of forensic science activities from law enforcement environments. Actually, what lies behind this tension is a very old dilemma about the information needed to interpret traces. Do we favor the use of contextual information for driving the reasoning pattern and selecting relevant actions, or do we avoid it because it may influence judgment and possibly lead to miscarriages of justice? Or can we combine both?

Forensic science suffers from some confusion. It often remains confined inside arbitrary barriers erected by some police organizations, other agencies in the justice system, or the logic of the market. This is a result of the environment in which forensic science developed and which has governed its growth and activities historically. Whether it can now capture how security and justice paradigms may coexist to produce forensic intelligence tasks remains to be seen. This point can be illustrated by, for example, the decision to increase the proportion of cases attended by crime scene examiners in high-volume crime. Two possible intentions may direct this decision: it is a decision in response to a demand from the public who are concerned that no crime scene examiner is engaged when they are victimized, implying that the police do not consider their case seriously; it is a decision that logically fits within a strategy of providing the many investigative, intelligence, and justice processes with a greater quantity of information. In the first situation, the policing strategy targets the improvement of the image of police work independently of the quality and quantity of information collected and its contribution to the treatment of crime problems. This strategy is often adopted for political benefit or to address the community policing objective of reassuring the public, rather than as a response to crime phenomena. The second option may be more difficult and demanding intellectually but is the only logical and ethical policy.

In such uncertain environments, contradictions arise that place forensic scientists in a less than advantageous position

where procedures are to be followed in a routine manner. This prevents them from going beyond or thinking 'out of the box' when solving forensic problems which are, by their very nature, singular.

Conclusion

Forensic intelligence calls for a return to the very fundamental object studied by forensic science: the trace. It comprises methods, techniques, and inferential activities that all combine to bring information to decision makers in policing at all levels (strategic, operational, and tactical) within a systematic and integrated framework.

Forensic science should therefore be seen as an autonomous discipline. Its major contribution should be to bring support to decisions in many environments, rather than exclusively to serve the justice system and court processes.

Nevertheless, progress is slow because of a traditional resistance to innovation and the expectations from justice agencies that drive the outcomes of police organizations and forensic laboratories. Intelligence-led strategies develop slowly and with difficulty, which in turn hampers the progress of forensic intelligence. Moreover, even when an intelligence culture develops within an organization, an awareness of the potential for traces to support decision-making remains low. A change of paradigm is needed in which the trace left by an offender is considered as a basic element of the crime puzzle, like corners and edges, on which to build the overall picture.

Overview and Meaning of Identification/Individualization

C Champod, University of Lausanne, Lausanne, Switzerland

The Identification Process: A Reduction Process to a Single Source

The definition of identification in forensic science may differ largely from the one accepted in science, where the term 'identification' is simply used to describe the attribution of an object to a definite class. In criminalistics, the identification process seeks, ultimately, individualization. For forensic scientists, identifying an object means it is possible to distinguish this object from all the objects considered. In the forensic literature, the problem of identity of source is often and unfortunately treated by reference to 'class' and 'individual' characteristics (Table 1).

Comparisons that lead to agreement, only in terms of class characteristics (without significant differences), will end up with 'group identification' conclusions. Only when corresponding individual characteristics are present in conjunction with class characteristics, positive identification or individualization conclusions can be drawn. The definitions of 'class' and 'individual' characteristics are only conventional ways of describing selectivity.

However, the problem of inferring identity of source is more complex than a simple dichotomy between class and individual characteristics. As illustrated in Table 2, practitioners have traditionally distinguished the forensic fields that can lead to individualization and those leading rarely (in the present state of the art) to individualization, but more commonly to corroborative information of various strength.

The arguments developed in this article should bring the reader to realize that these contrasts (class vs. individual; corroborative vs. individualization) have no foundation. All identification disciplines constitute corroborative information of strengths that change from one discipline to the other as a function of the discriminative ability of the features revealed by the unknown mark under consideration.

In most forensic scenarios, the pool of potential sources is not entirely forensically investigated, but the inquiry will focus on a limited set of suspected sources. Had all the other sources but the suspect been excluded by forensic examination, then identity of source would be declared applying a trivial deductive argument (regardless of the features considered). But in typical casework, such a deductive process is not feasible, and therefore, identity of source must be inferred and the process is probabilistic in nature. We had to wait for Kwan in 1977 to provide a reasoned account of how criminalists infer identity of source. The identification process can be seen as a reduction process, from an initial population to a restricted class or, ultimately, to unity. The initial population constitutes control objects or persons, depending on the type of evidence. The process combines two factors:

- A relevant population of control persons or objects defined by its size (and/or other particularities). Put in another way,

each member of this population of sources can be seen as a possible source.

- A reduction factor resulting from the combination of concordant characteristics of determined selectivity. In fact, the reduction is proportional to the rarity or relative occurrence of these observed characteristics in that relevant population. We will call it at times, the match probability. As Kwan indicates: "this is the sheer rarity of a feature that is important as rarity of that feature with respect to the set of suspected sources being considered. It is important to stress that rarity is relative to the situation at hand."

With respect to the size of the relevant population, an 'open set' framework will be distinguished from a 'closed set' framework.

- The open set framework implies that the population at large is considered; meaning, for example, that all living persons on Earth or all produced objects on Earth are taken into consideration as potential sources. Given the population considered here, the term 'Earth population paradigm' is sometimes used synonymously to describe this framework.
- The closed set framework corresponds to a situation in which the number of control objects or persons is restricted to a specified set of suspected sources (e.g., by taking into account other evidence available from the inquiry describing the putative sources).

To illustrate the identification process graphically, we will assume the following generic case leading to an association. A mark is found in association with a crime. Following inquiry, a potential source is submitted to the laboratory for examination. The comparison shows that the recovered and the control materials share some common features (named hereinafter forensic findings or results). Moreover, there is no significant difference to be accounted for. It is worth noting that the arguments will hold, without loss of generality, when the features would guide toward exclusion. Given this scenario, the identification process may be illustrated as shown in Figure 1. The identification process (in an open set or a closed set framework) is a narrowing-down process, reducing the number of possible sources or hypotheses.

The hypothesis that a designated suspect or object is the source is considered 'proven' by showing that all alternative hypotheses that could explain the phenomenon at hand are excluded. The term 'proven' is used loosely here as the decision process itself will be covered in the next section.

The importance of selecting features judiciously cannot be overemphasized. The criteria for selecting features fall into five areas (without taking cost into account): distinguishability, high intersource-to-intrasource variance, known variance in time, normalization (standardization), and independence. Of course, each field is focused on different features and it is worth giving a few examples of adequately chosen features in some forensic areas (Table 3).

Table 1 Distinction between 'class' and 'individual' characteristics in some identification fields

Field	'Class' characteristics	'Individual' characteristics
Fingerprint identification	General pattern, ridge count, ridge tracing	Minutiae, pore structure, ridge structure
Shoemark identification	General patterns, size, manufacturing characteristics	Cuts, accidental acquired characteristics, transient wear features
Bullet identification	Caliber, number of grooves/lands impressions, angles of grooves/lands impressions, width of lands/grooves	Striations on grooves/lands impressions

Table 2 Classification of forensic evidence types with respect to their identification capabilities

Individualization	Corroborative
Fingermarks (more generally marks left by friction ridge skin)	Microtraces (glass, paint, hairs, fibers)
Footwear marks	Biological fluids (now mostly DNA)
Earmarks	Drugs and toxicology
Toolmarks and firearms	Explosives and fire residue analysis
Handwriting and signature Examination	Soils

**Figure 1** Schematic description of the identification process (here focused individuals, but will apply by analogy to objects as well).

The Inferential Schemes

In practice, for obscure reasons, the identification process leading to individualization is generally operated in an open set framework. The Earth population paradigm prevails. This leads to two types of inferential schemes: toward an individualization decision, complemented, and, when allowed to the practitioners, by the provision of corroborative information.

Table 3 Features used to identify in some forensic fields

Field	Features used to characterize or (ultimately to individualize)
Fingerprints	General pattern, minutiae, pores, and ridge structures
Shosoles	Manufacturing characteristics (pattern, size, peculiarities of the manufacturing process) and acquired characteristics (wear features, cuts)
DNA	Various polymorphic loci on the DNA molecule
Microtraces	Optical (color, microscopic features, refractive index), physical (size, length, diameter), and chemical characteristics (FTIR, elemental composition, pyrolysis coupled with gas chromatography, etc.)

Individualization Decision

For Tuthill and George:

The individualization of an impression is established by finding agreement of corresponding individual characteristics of such number and significance as to preclude the possibility (or probability) of their having occurred by mere coincidence, and establishing that there are no differences that cannot be accounted for.

Following this definition, the size of the control population is indeed systematically set to its maximum (the open set framework). This practice is generally used and implicitly required in fields like those of fingerprints, footwear marks, tool marks, or firearms. For example, for footwear/tire marks, SWGTREAD (Scientific Working Group for Shoeprint and Tire Tread Evidence) indicated in 1996 that the individualization opinion means that 'the particular shoe or tire made the impression to the exclusion of all other shoes or tires.'

The conclusion of individualization is then an opinion, a statement expressing the view that the chance of observing on Earth another object or person presenting the same characteristics is considered as negligible. For the expert, at this stage, he/she cannot conceive that any contrary evidence (e.g., an alibi) will ever shake his/her certainty. As to the mechanism used by examiners to reach this belief of certainty, Stoney describes a decision analogous to a 'leap of faith.'

The move from a given probability of association to a decision of individualization is fully described by Biedermann, Bozza, and Taroni in the context of formal Bayesian decision theory. Formally, the decision requires, after the establishment of a probability of association, the use of a gain/loss function amounting to weighing of the benefits and costs associated to the possible decisions. The schematic description of the identification process can now include this decision step toward individualization (Figure 2).

Overall, the decision scheme calls for the following comments:

- It is odd to set the size of the relevant population at its maximum a priori in all cases. Indeed, the number of potential sources from which the mark could originate may be restricted by other evidence available (witness testimonies, other forensic evidence, etc.). Presenting the forensic findings in an open set framework is too conservative, adopting systematically the extreme defense attorney's position in trying to make the court believe that all persons

Figure 2 Schematic description of the identification process completed with a decision of individualization.

or objects on Earth could be the origin of the marks of interest. The forensic scientists or the courts rarely question this systematic reliance on the Earth population paradigm.

- The decision threshold, the leap of faith, is in essence a qualification of the acceptable level of reasonable doubt (weighted by a gain/loss function) adopted by the expert. Jurists may interpret this threshold as an expression of the criminal standard ‘beyond reasonable doubt’ regarding the issue of the identification. However, courts have generally accepted delegating that burden. The recent calls for caution were addressed to the perceived 100% factual certainty that the term ‘individualization’ may convey, but not on the fact that the scientist decides on the source issue. As long as the scientist is not claiming to 100% certainty or an establishment of an uncontroversial fact, courts will generally not object to him/her expressing an opinion of individualization. This leads to the development of phraseology of the kind: ‘he is the bitter to a reasonable degree of dental certainty’ or ‘the bullet is identified to that barrel to a reasonable degree of ballistic certainty.’

The fact that individualization is a decision that accounts for a probabilistic assessment starts to be recognized by practitioners. For friction ridge skin, SWGFAST in 2011 defines individualization as the “decision by an examiner that there are sufficient features in agreement to conclude that two areas of friction ridge impressions originated from the same source. Individualization of an impression to one source is the decision that the likelihood the impression was made by another (different) source is so remote that it is considered as a practical impossibility.” However, the framework (‘open set’ or ‘closed set’) and the gain/loss function (admission of a cost/benefit analysis before taking the decision) remain completely implicit. As soon as it is made explicit, the author will argue that such a decision scheme is no longer tenable in forensic science.

Provision of Corroborative Information

In some forensic fields (typically fingerprints), practitioners have voluntarily excluded corroborative statements – other than exclusion and individualization – from their conclusions. All results between these extremes are classified as ‘inconclusive.’ There is no logical reason for avoiding such corroborative

statements and the author would support any move to bring corroborative information in these fields. Each piece of information is relevant if it tends to make the matter that requires proof more or less probable than otherwise. Hence, a piece of information that only approaches the extremes constitutes relevant information that should not be ignored, and it is necessary for the expert to express a probability statement, verbally or numerically, which attempts to assess the weight of the forensic findings.

Examiners have expressed the meanings of corroborative conclusion terms pragmatically. Their respective meaning relates somewhat to their power of reduction of the initial population. An agreement on the terms has been achieved in some disciplines. For example, in the area of footwear marks, the range of recommended corroborative terms is: *probably made, could have made, inconclusive (could not be determined), and probably did not make*. Another example is the ASTM standard E 1658–04 for document examination that enforces the terms: *strong probability (highly probable, very probable), probable, indications (evidence to suggest), no conclusion (totally inconclusive, indeterminable), indications did not, probably did not, and strong probability did not*.

This identification process scheme leading to the provision of corroborative information is illustrated in Figure 3. Note that there is no decision required here, the conclusion being only a verbal translation of the position reached down the funnel (combination of the population of controls with the reduction factor).

This inferential scheme calls for two comments:

- Conversion between the end position in the reduction process and the verbal statement is never declared or explained. This naturally leads to obvious variations between examiners when assessing the same case.
- Allegiance to the Earth population paradigm is either not questioned or the logic of the terminology is justified using a highly debatable 0.5 prior probability as discussed by Biedermann, Taroni, and Garbolino. Adopting a prior probability of 50% is akin to consider that, outside any consideration of the case circumstances, only two potential sources are considered initially, the source under investigation being one of them. The adoption, by the forensic scientist, of such a default starting position is highly prejudicial to the source under investigation.

Figure 3 Schematic description of the identification process leading to the provision of corroborative information.

Relationship with Probabilities

Individualization

From a probabilistic point of view, to conclude individualization would mean that the probability ($\Pr$) of the event, here the event is 'identification,' after examining the forensic material at hand, is equal to 1. Because of the probabilistic nature of the identification process, such a probability of 1 is an absolute that cannot ever be reached. Hence, the examiner expresses an opinion of individualization when this probability is so near 1 that it maximizes his/her implicit expected utility. It is worth asking ourselves the order of magnitude of that probability (and that of the relative occurrence of the features) in the mind of an examiner at the moment of its decision.

This probability of individualization, given the forensic findings, can be represented in the form $\Pr(\text{ID}|\text{E})$, where ID denotes the event individualization, which is uncertain, and E denotes the information available, the results of the forensic examination, which has been taken into account. In this way, the vertical line can be seen as shorthand for the word 'given.'

We have seen, at this stage, that the identification process is related to the specificity of the mark under examination – its relative occurrence in the relevant population – and the size (N) of the relevant population being considered. The probability that we are interested in is then conditioned on both E and N and becomes $\Pr(\text{ID}|\text{E}, N)$.

We can derive the probabilities of interest by simply using the odds form of the Bayes theorem.

$$\frac{\Pr(\text{ID}|\text{E}, N)}{\Pr(\overline{\text{ID}}|\text{E}, N)} = \frac{\Pr(\text{E}|\text{ID}, N)}{\Pr(\text{E}|\overline{\text{ID}}, N)} \frac{\Pr(\text{ID}|N)}{\Pr(\overline{\text{ID}}|N)} \quad [1]$$

Let us denote $\Pr(\text{E}|\overline{\text{ID}}, N)$, the relative occurrence of the features, by γ , note that $\Pr(\text{ID}|N) = 1 - \Pr(\overline{\text{ID}}|N)$ and $\Pr(\overline{\text{ID}}|\text{E}, N) = 1 - \Pr(\text{ID}|\text{E}, N)$, and finally assume for the sake of the example that $\Pr(\text{E}|\text{ID}, N) = 1$ and $\Pr(\text{ID}|N) = 1/N$, we obtain by rearranging eqn [1]:

$$\Pr(\text{ID}|\text{E}, N) = \frac{1}{[1 + (N - 1)\gamma]} \quad [2]$$

$$\gamma = \frac{1 - \Pr(\text{ID}|\text{E}, N)}{\Pr(\text{ID}|\text{E}, N)(N - 1)} \quad [3]$$

At this stage, a note on the assumption of a prior probability $\Pr(\text{ID}|N)$ equals to $1/N$ is necessary. The Earth population paradigm invites to assign to each member of that population a prior probability higher than 0. Indeed, by definition, to be considered in the pool of possible sources requires the prior probability for each source to be higher than 0. The form of the probability distribution that should be adopted is not a trivial matter. However, if a forensic scientist operates within an open set framework, in the absence of any information, and in order to maintain fairness between all potential sources, he/she will have no choice than to adopt a uniform prior between all members, hence the suggestion for $1/N$. In any case, that constraint will be relaxed later in this article.

We turn back to the question of the orders of magnitude of $\Pr(\text{ID}|\text{E}, N)$ and γ in the mind of an examiner at the moment of its decision. If the population is set to $N = 7$ billion (including the control) as suggested by the Earth population paradigm, and $\gamma = 1$ in 7 billion, then, using eqn [1], $\Pr(\text{ID}|\text{E}, N)$ is very close to 0.5. This means that if you have a control object or person at hand with such a rare relative occurrence, the probability that you have the wrong one is about 0.5! It means that in order to have probabilities on the individualization higher than 0.5, we need match probabilities γ that are much lower than the inverse of N , the size of the considered population. This is counterintuitive, but correct in the context of the present Earth population paradigm.

If we accept that $\Pr(\text{ID}|\text{E}, N)$ must be above a certain threshold value in order to declare an individualization (hence maximizing the expected utility function), then it is possible to calculate the match probability (γ) that must be considered to achieve such a preset value. If $\Pr(\text{ID}|\text{E}, N)$ is fixed at 0.9998 – meaning 'I want to be sure at 99.98% of the individualization' – with $N = 7$ billion, using eqn [3], we see that γ must be equal to $2.9\text{E-}14$, which represents 1 in about 5000 times the size of the initial population of 7 billion.

If a conclusion of individualization (according to this threshold and in an open set framework) must be at least the expression of such a small match probability in order to

maximize the gain function, then we face the prospect of articulating probabilities out of reach from today's systematic research. Taking fingerprints as an example, the recent published statistical research would allow us to quote confidently match probabilities in the order of one in a billion. Articulating any smaller number (down to the probability of zero) is difficult if not impossible to support.

The above treatment tends to demonstrate that decisions of individualization taken by practitioners cannot be made in the open set framework, but they certainly operate implicitly in a undefined closed set. The probabilistic analysis of corroborative information will reinforce that point.

Corroborative Information

What is the probabilistic meaning, in the open set framework, of conclusions such as 'it is possible (or probable or highly likely) that this print/mark has been made by this particular item'? Such verbal scales can be translated into numbers expressing $\Pr(\text{ID}|E, N)$. These terms are understood quite uniformly (in a numerical conversion) by forensic scientists or jurists. The numerical conversion is given in Table 4 (columns 1 and 2). From these probabilities, their corresponding match probabilities (γ) can be derived, using eqn [3], considering an open set framework ($N=7$ billion) as shown in Table 4 (column 3).

The analysis of Table 4 leads to a paradox. In the open set framework (as claimed to be adopted mostly all forensic fields), the rarity of the shared features, which corresponds to the most negative verbal statement (*likelihood bordering certainty for the exclusion*), is quite small ($1.4\text{E-}7$). For the court, every piece of information that would lead to such small match probability will be considered as highly indicative (by analogy with DNA findings, for example). Hence, the verbal statement proposed here does not make this evidential value very clear. To escape this paradox, forensic scientists could be tempted to adjust the size of the relevant population, hence to pass from an open set framework to a closed set framework.

Table 4 Relationship between verbal statements in qualified opinions and the probability of identification along with the corresponding match probabilities γ (assuming a relevant population of 7 billions, including the control)

Verbal statement	$\Pr(\text{ID} E, N)$ (%)	Match probability γ
Terms in favor of individualization		
Likelihood bordering to certainty for the individualization	99.98	2.9×10^{-14}
Highly (very) likely	98	2.19×10^{-12}
Likely	85	2.5×10^{-11}
Very well possible (plausible)	75	4.8×10^{-11}
Possible	60	9.5×10^{-11}
Terms in favor of exclusion		
Possible not	40	2.1×10^{-10}
Very well possible (plausible) not	25	4.3×10^{-10}
Not likely/unlikely	15	8.1×10^{-10}
Highly (very) unlikely	2	7.0×10^{-9}
Likelihood bordering certainty for the exclusion	0.1	1.4×10^{-7}

As aforementioned, some have even suggested to adopt a default prior probability $\Pr(\text{ID}|N)$ of 0.5 – qualified as fair and neutral – in every case!

The analysis of these two inferential schemes with their counterintuitive and paradoxical consequences shows that there is an urgent need to find a common, coherent, and harmonized framework to assess such information. The proposal below advocates the use of a Bayesian model to properly position and convey the value of identification information.

The Bayesian Framework for Evaluating Identification Findings

In the Bayesian framework, both closed set and open set situations can be handled; the open set constitutes a specific situation. From information gathered through normal investigation or through the use of a database, a limited number of people or objects, or a single person or object, can be pinpointed in a general or limited population. There is no way to go back along the time axis and deduce the identification. The only way to evaluate the strength of the forensic findings is to consider them from two perspectives: that the designated person or object is, or is not, the source. The Bayesian approach permits the revision of a measure of uncertainty about the truth or otherwise of an issue (here the individualization ID) based on new information. It shows how data can be combined with prior or background information to give posterior probabilities for particular issues. The following events can be defined from the previous example:

- I Some background information has been collected before the forensic examination. For example, data from police investigation, eyewitness statements, or data from the criminal historical record of the suspect will contribute to I. Typically this information will reduce the number of potential suspects or objects that could be at the origin of the mark
- E The features agreement (without significant differences) reported as the forensic results between the mark left at a scene and a person or object under examination
- ID The mark has been produced by this person or object in examination
- $\overline{\text{ID}}$ The mark has not been produced by this object or person, and another unknown person or object is at the origin of the mark. The definition of the two exclusive hypotheses (ID and $\overline{\text{ID}}$) requires consideration of the context of the case (the defense's strategy, for example); they are not always as straightforward or exhaustive as could be deduced from our example

The Bayes' formula (eqn [4] – similar to eqn [1]) shows how prior odds on ID are modified by the results E to obtain posterior odds on the issue:

$$O(\text{ID}|E, I) = \frac{\Pr(E|\text{ID}, I)}{\Pr(E|\overline{\text{ID}}, I)} O(\text{ID}|I) \quad [4]$$

where $O(\text{ID}|I)$ =the odds on the individualization before forensic examination, the prior odds on ID equal to the ratio $\Pr(\text{ID}|I)/\Pr(\overline{\text{ID}}|I)$; $O(\text{ID}|E, I)$ =the odds on the

individualization given the results E , the posterior odds on ID equal to the ratio $\Pr(ID|E, I)/\Pr(\overline{ID}|E, I)$; $\Pr(E|ID, I)$ = the probability of the shared features between the mark and the control, given that the mark has been left by the suspect or object in examination (ID is true) – generally, this value is close to 1, but this is not a requirement; $\Pr(E|\overline{ID}, I)$ = the probability of the shared features between the mark and the control, given that the mark has not been left by this person or object ($\overline{ID}$ is true); γ has been used throughout to refer to this probability.

In this Bayesian perspective, the open set framework covers the situation where the prior odds are estimated in reference to the total population possible (I represents no prior knowledge at all); any other situation with an estimate of the prior odds can be viewed as a closed set framework.

Compared to eqn [1], the only difference is that I is used instead of N . It was previously suggested (eqn [2]) that the prior probability was strictly in relation to N . Here, N is omitted and replaced by I to stress upon the fact that the prior probability will depend on more factors than on only N , that is, investigation, eyewitness statements, or data from the criminal historical record of the suspect, etc. In fact, each case bears its own specificity in this regard. But, generally, these data are not known to the forensic examiner and are outside his or her province. Hence, the assessment of the prior odds remains the confines of the fact finder (judges, members of the jury, etc.). As a consequence, before the presentation of the expert results, it will be up to the fact finder and not the forensic scientist to assess the prior odds on the individualization. By the way of consequence, it is up to the fact finder to take the final decision (and applying their own gain/loss function).

The framework itself, here, does not belong anymore to the forensic scientist but belongs to the fact finder. The statement (numerical or subjective) made to the court by the forensic scientist should then only be the expression of the reduction factor to be applied to the prior odds (opinion of the court without the knowledge derived from the scientific results). Without the information about the prior odds, it is not possible for the scientist to state the fact itself (the probability that this particular person or object has produced this mark): he can only state the degree of support given to this hypothesis (or version) versus the alternative. The strength of the forensic findings is then given by the probability of observing them under two chosen propositions. This ratio is called the ‘likelihood ratio.’

The statement given by the scientist alone is not sufficient to decide on the issue. The scientist’s statement is then completely different from assessing the fact itself. The concept of the

weight to be assigned to forensic results is therefore relative: it shows how observations should be interpreted as support for ID versus its counterpart, but it makes no mention of how those observations should be interpreted as evidence in relation to ID alone. Therefore, the same piece of information may be an insufficient proof for a fact finder in one context, but may be the factor essential in clinching the case in another. The odds, in favor of the individualization itself, that the person or object in examination has produced the mark given the circumstances of the case (background I) and the observations made by the forensic scientist (the results E) is a judgment based on posterior odds combined with the results. The essence of the decision on the individualization remains the province of the fact finder. This logical tool permits an understanding of how events interact mathematically. It clarifies the position of the scientist as well as that of the judge, and defines their relationship. The scientist is concerned solely with the likelihood ratio, whereas the fact finder deals with the odds on the individualization (Figure 4) and ultimately the associated decisions.

The Bayesian model helps us to understand the respective duties of the fact finder and of the forensic scientists (Figure 4). Our schematic representation of the identification process can then be refined, taking into account the Bayesian perspective (Figure 5).

Conclusion

The traditional inferential schemes for the question of identification of source have been presented. They lead either to decisions of individualization/exclusion or to the provision of corroborative opinions (possible, probable, very probable, etc.). Both of these schemes are operated with reference to a relevant population size set to its maximum in what has been called an open set framework (or the Earth population paradigm).

These schemes perpetuate the vision that forensic scientists can deal – sometimes without being aware of – with prior or posterior probabilities on the issue and with gain/loss function when making decisions. Moreover, the probabilistic relationship between verbal opinions and probability of occurrence of the shared features has shown counterintuitive and paradoxical consequences.

It appears legitimate to question if these practices are reasonable for forensic cases. Another scheme, the Bayesian interpretation framework, overcomes most of these difficulties, in

Figure 4 Schematic representation of the Bayesian framework positioning the actors of the judicial system.

Figure 5 Schematic representation of the value of forensic findings (or results) in the identification process.

particular, by relaxing the necessity of adopting an open set framework and avoiding the final decision step. It provides a coherent way of assessing and presenting identification evidence. From a logical point of view, the strength to be attached to forensic findings is essentially relative to the case and its value is best expressed using a likelihood ratio. The question of the size of the relevant population – which impact on prior probabilities – and decision thresholds are finally outside the province of forensic scientists but rightly belong to the fact finder.

Glossary

Heuristic Heuristic refers to experience-based techniques to solve problems, to learn, and to discover. Heuristic methods are used to speed up the process of finding a satisfactory solution, where an exhaustive search is out of practice. Examples of heuristic methods include

‘rule of thumb,’ educated guess, intuitive judgment, or common sense.

Inference Act or process deriving logical conclusions from premises known or assumed to be true. The drawn conclusion is also called inference. Laws of valid inference are studied by logic.

Semiotic Theory and study of signs and symbols.

General Consideration and Semiotics

Forensic science is at the core of criminal investigations. From crime scene to courtroom, a variety of forensic personnel play a variety of roles in forensic investigations: crime scene investigators (CSIs), scientists, pathologists, investigators, and even investigative magistrates in inquisitorial justice systems. Because each forensic discipline uses different techniques and each forensic scientist has different priorities in his or her role, tensions occur between them, and the position of science remains unclear. Methods of reasoning used by these forensic professionals during scientific investigation of criminal cases are complex; an understanding of the various inferences involved could improve the process.

The crime, and therefore the crime scene, is at the core of forensic science: the case begins with the crime and most of the evidence either is recovered from or refers to the crime scene. Major questions arise during the collection of evidence: How do CSIs determine which trace should be collected? How does a trace become evidence? How is a trace linked to a source, an item of evidence? Various processes of reasoning inform these and similar decisions through the forensic process. First, how does a CSI, collecting evidence at a crime scene, decide which trace should be collected as evidence? Traces, both innocent and criminal, exist before the investigation begins and contribute to the CSI’s perception and description of events and interactions between persons. Locard’s and Kirk’s principles assert the fundamental value of the trace, inducing the need to search for it. The search for traces at crime scenes can be done according to three different levels of analysis.

- *Physical level*: This level addresses the affinity between materials and matter that facilitates transfer and persistence. For instance, which substrates best facilitate the detection of various types of traces?
- *Situational level*: This level deals with the knowledge of criminal situations and their consequences on the exchange of evidence; that is, what kinds of evidence are most likely and useful in, for example, sexual assaults?
- *Intelligence level*: This level takes into account recurrent phenomena, known series, specific problems, and the local crime situation. This is a strategic level of information.

According to Kirk, the goal of analyzing physical traces is to establish a link between the traces and their potential sources, which is probabilistic by nature due to the various uncertainties attached to the items, processes, and traces in question. Because of the diversity and specificity of each type of trace, and what can be inferred from each, specific knowledge is necessary to fully exploit and compare them. As a result, specialists in differing areas of forensic science must work together to conduct the comparisons. Finding and recognizing traces as relevant data or pieces of evidence constitute the first challenge for scientific investigators at a crime scene. Because forensic science is overtly a historical process, evidence is necessary to determine what may have occurred during the commission of a crime. Therefore, it is important to understand the different types of inferences used to determine which traces are of value as evidence for solving an investigation.

Inferences

Paolaggi and Coste consider that methods of thought are brought into play according to the level of awareness involved and separate them schematically. First are methods of thought of explicit use, which are clear mental constructions where reasoning is specifically expressed. This category includes the following types of reasoning: deductive reasoning, inductive reasoning, abductive (also called retroductive) reasoning, hypothetico-deductive reasoning, descriptive reasoning, causal reasoning, probabilistic reasoning, analogical reasoning, and reasoning helped by pragmatic algorithms. Apart from the hypothetico-deductive approach, no other kinds of mental constructions will be discussed further in this article. Second are methods of thought of implicit use which are forms of reasoning that do not involve a formalized reasoning, instead employ a type of thinking called heuristics. This category includes heuristics (representativeness, availability, adjustment, and anchoring effect), individual rigorous types of thought, and enlightened judgment.

Heuristics

Heuristics are experience-based techniques for generating inferences, such as that do not rely on formalized reasoning. It could be compared to a type of human inference skill that is a

'shortcut,' instead of rigorous analytical reasoning, that makes complex judgments easier. One example of a heuristic is the familiarity heuristic: If asked which city, Munich or Dusseldorf, has the greater population, those who do not know the actual population values will answer 'Munich' because they have heard of Munich more often; they would be correct (Munich has about 1.3 million people, while Dusseldorf has about 600 000). The impact of heuristics on the evaluation of evidence has been studied by Goldman. Goldman points out that jurors typically use heuristics to evaluate the elements of evidence presented to them. Goldman considers heuristics an alternative to Bayesian inference.

Hypothetico-Deductive Reasoning

The hypothetico-deductive reasoning method has been accepted by many authors in the field of forensic science. This method of reasoning concludes the acceptability of the inferred causal hypothesis (the crime event or source) through inductive experiments (published or simulated). As Catellin observed, the hypothetico-deductive method is an exploratory logic that minimizes surprise and calls for imagination in the formulation of ideas: it combines abduction, deduction, and experience (weak or strong induction). Hypothetico-deductive reasoning is excellent for reasoning in medical science, where it can be used to formulate and test the most plausible hypothesis after a patient's symptoms have been observed. Crispino, referring to Peirce, summarizes the relationships among deduction, induction, and abduction in [Figure 1](#), which defines primary logical inferences through their premises.

Two hypothetico-deductive reasoning processes that are used by pathologists and in the medical field could be of interest to forensic science. For familiar situations, the personal (education and experience) knowledge base of the practitioner leads him to a preferred hypothesis for his patient. For

unfamiliar situations, if a familiar treatment does not work, or facing an unknown situation, the pathologist takes recourse to a new hypothetico-deductive process.

Investigation and Evaluation

According to Jackson and colleagues, the scientific work on a criminal case can be divided into two phases: investigation and evaluation. The evaluation phase can be further broken down into two stages: pre-evaluation and post-evaluation. The pre-evaluation process of cases settles priorities according to facts that must be clarified, the explicit needs of the investigative or judicial authorities, the budget allocated for the case, and time constraints. The post-evaluation process is used for complex cases in order to coordinate the experts' opinions on specific pieces of evidence, and to advise the trier of fact on the relative strength of evidence, including the way to introduce and understand the evidence in the courtroom.

It is important to develop systematic approaches to crime scene processing during the first phase of the investigation. Checklists, protocols, plans of researches and sampling, sketches, films, and photographs are all helpful at this stage. Defining physical limits within the crime scene will help protect evidence and, by dividing the scene into manageable sections, will assist in detection and collection of traces. Sketches, films, and photographs provide record of the chain of custody, and visually preserve the crime scene for future reference. These visual records of the crime scene will allow persons who were not present at the crime scene to understand where the trace was collected from for reconstruction purposes. These visual tools should be regarded as work support, and should not substitute for critical thinking.

Hypotheses can be generated during the initial phase of investigation by observing the crime scene and available facts. In the pre-evaluation phase, knowledge is compared to a new but generalized situation. Further on during the investigation – for instance, of a burglary – the crime can be defined more or less concisely and clearly. Frequently, hypotheses generated through inference can help CSIs determine where to search for traces: for example, possible points of access, potential routes of escape, and spaces the perpetrator may have occupied. The discovery (or lack of discovery) of traces will confirm or deny these hypotheses. As hypotheses are confirmed and discredited, the events of the crime will become clearer and more hypotheses can be generated, which will, in turn, make the circumstances even clearer.

Complex investigations are best examined through a hypothetico-deductive framework. Because this model must be based on unique criminal investigations and cannot be constructed independently, modalities of inputs and outputs within the field of the criminal case inquiry have to be defined. CSIs and scientists can use observation and physical data to generate hypotheses by abduction. These hypotheses should be carefully expressed so that their limitations are explicit, particularly when sharing hypotheses with detectives.

Figure 1 Primary logical inferences defined through their premises (according to [Crispino, 2008](#)). Translating the basis of each arrow along its axis weakens or strengthens the created inference.

Bayesian Reasoning

Jackson and colleagues proposed the use of a Bayesian framework of reasoning at the crime scene for the purpose of crime

scene management. Although the authors acknowledge that relatively few facts will be available at this point in the investigation, they propose generating probable hypotheses through the following process: observation, detection, generation of plausible hypotheses, allocation of a priori probabilities that are relevant to the case at hand, and assessment of the likelihood of each hypothesis. When this has been completed, the CSI should begin a second phase of observation, leaning on complementary research, detection, and observations. Finally, a posteriori probabilities are drawn for all hypotheses before the results are presented to the detective in charge or the trier of fact.

Synthesis

Figure 2, from Schuliar, summarizes various models of reasoning that are relevant to criminal investigation.

Consistent partnership between forensic scientists and investigators would benefit investigations. To fully participate in such a partnership, forensic scientists would have to:

- examine evidence from a scientific point of view;
- determine priorities for technical measures;
- collaborate with scientists in the different laboratories;
- inform detectives and parties of scientific results and its significance in a timely fashion;

- advise investigators of new scientific opportunities for investigations in progress; and
- analyze and interpret results in context.

Evidence should be reinterpreted at various stages of the investigation to requalify the significance of that evidence in light of new facts. This approach acknowledges the relevance of reconstructionist views held, for instance, by De Forest, Gaensslen, Lee, Saferstein, Houck and Siegel, and Chisum and Turvey. Reconstruction can be defined as the sequencing of events, in time and space, based on trace evidence. This technique requires coordination between forensic scientists and investigators.

The Interest of a Coordination

The need for coordination throughout an investigation is essential to properly assess the evidence. Such a collaboration is even more important in cases of serious crime, in which a greater amount of more complicated evidence is likely to be analyzed.

Several levels of coordination are required:

- *Coordination of crime scene management*: The search for traces has to be made at physical, situational, and intelligence levels. Trace evidence collected at a crime scene can shape an investigation, and determine investigators' subsequent evidence and information collection requirements.

Figure 2 Proposed model of inferences involved from crime scene to Court (according to Schuliar, 2009).

- *Generation of hypotheses*: Hypotheses should be generated by a person who has a body of knowledge about the case and the capacity to think critically.
- *Testing of hypotheses*: Probable hypotheses will have to be tested, evaluated, and assessed.
- *Coordination between forensic scientists and investigators*: Scientific coordination is essential not only during the reconstruction and the preparation for trial phases, but also during the evaluation one.

Conclusion

Comparative analysis and identification often rely on the forensic scientist's experience, rather than the use of explicit logical inferences, empirical studies, or published research. Forensic scientists are able to make interpretation that is apparently based on scientific methods, but is, in reality, based on what they feel or believe. A complete understanding of methods of reasoning is needed for scientific investigation, evaluation, and coordination. This understanding should include the process of heuristics through the knowledge of mechanisms of fallacious reasoning.

Glossary

Alignable differences Differences that are connected to the hierarchical system of relatedness of two or more things.

Analogous trait A characteristic that is similar between two things that is not present in the last common ancestor or precedent of the group under comparison.

Analogy A cognitive process that transfers information or meaning from one subject (the analog or source) to another subject (the target).

Diagnosticsity The degree to which traits classify an object.

Homologous trait A characteristic shared by a common ancestor or precedent.

Nonalignable differences Differences with no correspondence at all between the source and the target.

Introduction

Analogy, and its more specific relative comparison, is a central component of human cognition. Analogy is the process behind identification of places, objects, and people and plays a significant role in many human mental operations, like problem solving, decisions, perception, memory, and communication. Some researchers, including Hofstadter, have even argued that cognition is analogy. Likewise, the cognitive process of analogy and the method of comparison lie at the heart of the forensic sciences. The ability to compare is predicated on some sort of classification (more properly, a taxonomy) that results in classes, groups, or sets.

Aristotle is considered the first to approach comparison as a way to arrange the world. His attempt to codify the process raised, however, an intractable problem that would only be addressed later: the classification of living things. Comparison, by itself, is a minimal technique, at best. A classification system – a taxonomy – is a prerequisite to a fuller comparative methodology. Comparative anatomy, one of the earliest formal applications of the method, goes beyond mere representation (mere comparison, that is) to explain the nature and properties of each animal.

The French naturalist Pierre Belon (1517–64) compared the skeletal structures of birds to humans in his book *L'Histoire de la Nature des Oiseaux* (*History of the Nature of Birds*, 1555; [Figure 1](#)), and, along with the Flemish naturalist Andreas Vesalius (1514–64), was one of the first naturalists to explicitly apply the comparative method in biology. Georges Cuvier (1769–1832) was the first to use comparative anatomy and taxonomy as a tool, not an end in itself, in his studies of animals and fossils. Cuvier was frustrated that biological phenomena could not be reconfigured into experimental conditions that would allow controlled testing, a difficulty common to many sciences (e.g., see Diamond). The intimate integration of a living organism's physiology with its anatomy created obstacles in teasing out and relating function to structure: Once an organism was dead and prepared for dissection, its function had ceased, thus confounding the relationship of form to function. Cuvier considered that careful examinations and the interrelating of

structures between specimens might also prove to be useful in revealing principles of observation and comparison. Perhaps the original scientist-as-detective, Cuvier, used scattered, fractured bits of information to reconstruct the prehistory of the Earth and its animals. In a 1798 paper, Cuvier wrote on his realization of the form and function of bones as it relates to the overall identifiable anatomy of an animal, leading to the recognition of the creature from which the bone originated:

This assertion will not seem at all astonishing if one recalls that in the living state all the bones are assembled in a kind of framework; that the place occupied by each is easy to recognize; and that by the number and position of their articulating facets one can judge the number and direction of the bones that were attached to them. This is because the number, direction, and shape of the bones that compose each part of an animal's body are always in a necessary relation to all the other parts, in such a way that – up to a point – one can infer the whole from any one of them, and vice versa. (Rudwick, 1998, p. 36)

This has been called 'Cuvier's Principle of Correlation of Parts' and is a central tenet in biology and paleontology. It is important to note that Cuvier claimed to be able to *identify* an animal taxonomically from a single bone, but not completely *reconstruct* it, as the above quote might imply. The reconstruction would only be possible with a sufficient number of bones representing the animal in question. The comparative method has been a successful cornerstone of science ever since, with new or emerging sciences, such as ecology, moving from the purely observational or descriptive approach to that of comparison through experimental or analytical methods.

A short discussion of terms in biology will help clarify concepts used in biological comparisons. The concept of homology, the same structure under every variety of form found in different animals, is the organizing foundation for comparative anatomy. Animals share homologous traits because they also share a common ancestor with the same or related trait. By contrast, analogous traits are similarities found in organisms that were not present in the last common ancestor of the group under comparison; that is, the traits evolved separately. The canonical example of the difference between homologous and analogous traits is the wings of birds and bats: They are

Figure 1 A drawing from Pierre Belon's 1555 book, *History of the Nature of Birds*, comparing the skeletal anatomy of birds to humans which is one of the first books using the science of comparative anatomy. Source: Wikimedia Commons, open source.

Figure 2 Hammers. All of the objects (a–f) are recognizable as hammers even though their components vary. (a) claw hammer; (b) framing hammer; (c) geological hammer; (d) ball-peen hammer; (e) rubber mallet; and (f) upholstery hammer. Source: Wikimedia Commons, open source.

homologous as forearms but analogous as wings; the latter structures evolved their functions separately. A homologous trait is termed a homolog. In biology, evolution and natural selection formed the system within which these relationships developed and were maintained, homogenized, or differentiated.

In manufacturing, other external and internal constraints form the basis for homologous and analogous traits through

design, function, form, and costs. Design follows from the product's intended end use, aesthetic concerns, and cost limitations. The function and form of an object tend to correlate and variances in design cluster around necessary and sufficient criteria. In **Figure 2**, for example, although the hammer heads, opposite sides, handles, materials, weight, shape, and components all vary, they are nonetheless identifiable as hammers. If **Figure 2** were finches, as Darwin studied in the Galapagos in

his historic voyage with the *Beagle*, the base process of taxonomy would be the same but the criteria and foundations – the history and causes – would obviously vary because of the vastly different processes that produce hammers and finches.

Broadly speaking, the supply chains and distribution networks of material goods are like the phylogenetic trees based on evolutionary descent. Regardless of whether the items are biological or manufactured, the independence of traits should not be assumed. Comparative studies that do not control for historical relationships through phylogeny or supply chains may imply spurious relationships (coincidences). Forensic science is unique in its use of the comparative method to reconstruct past criminal events and sourcing of evidence, either biological or manufactured (in essence, reverse engineering to a level of distribution or manufacturing resolution).

Analogy and Comparison Within a Forensic Process

Analogy is a cognitive process that transfers information or meaning from one subject (the analog or *source*) to another subject (the *target*); it thus implies at least two things: situations or events. The source is considered to be the more complete and more complex of the two and the target is thus less informative and incomplete in some way. The incompleteness may be due to any of several factors, alone or combined, such as damage, fracture, deterioration, or size. The elements or traits – including their relationships, such as evolutionary or supply chains – between the source and the target are mapped or aligned in a comparison. The mapping is done from what is usually the more familiar area of experience and more complete repository of information, the source, to the typically more problematic target.

Salience of the elements or traits is of prime importance: there are an innumerable number of arbitrary differences in either elements or relations that could be considered but are not useful given the question at hand ('Are both items smaller than the Empire State Building? Are they redder than a fire truck?'). Ultimately, analogy is a process to communicate that the two comparators (the source and the target) have *some* relationship in common despite any arbitrary differences. Some notion of possible or hypothetical connection must exist for the comparison to be made. As a forensic example, consider trace debris removed from the clothing of a suspect and the body of a victim: Although there may be no physical evidence (hairs, fibers, glass, soil, etc.) in common, the suspect's clothing and the victim's body have, at least *prima facie*, a common *relationship* (the victim is the victim and the suspect is a person of interest in the crime) until proven otherwise. Thus, common relations, not common objects, are essential to analogy and comparison.

The comparison process as a method makes several assumptions. First, the space in which the comparators are mapped is assumed to be Euclidean. Second, the method embeds the comparators in a 'space of minimum dimensionality' (Tversky) based on all observed salient similarities. Each object, *a*, is detailed and described by a set of elements or traits, *A*. Any observed similarities between *a* and another object *b*, denoted as *s(a, b)*, are expressed as a function of the salient traits they are determined to have in common. The comparison

Figure 3 A comparison of observed familiarities can be expressed as a function of three arguments, visualized here.

and any observed familiarity can be expressed as a function of three arguments (Figure 3):

- $A \cap B$, the features shared by *a* and *b*
- $A - B$, the features of *a* that are not shared by *b*
- $B - A$, the features of *b* that are not shared by *a*

Psychological studies show that people tend to pay more attention to the target (the comparator with less information) than to the source. In forensic science, this means that analysts would pay more attention to the samples from the crime scene or actors than to the known samples collected. This is true even though the known has more salience, because arguably it has more information and a documented provenance than the questioned sample. For example, a toy ship is quite similar to a real ship because most of the main features of the real ship are expressed in the toy (otherwise it might not be recognized as a simulacrum of its referent). A real ship, however, is not as similar to the toy ship because many of the features of a real ship are not expressed in the toy (due to function, scale, or safety, among other factors). The reason for paying more attention to the target is, first and foremost, to determine if there is sufficiency of salient information in the target for the comparative process to occur (see Vanderkolk for a discussion on this).

The main determinant of feature salience for comparative purposes is the degree to which they classify an object, that is, their diagnosticity. A feature that serves as the basis to reassign an object from one class to another class with fewer members is more salient than one that does not. Salience is hierarchical and is based on how many members of a class share that feature; the goal is thus to place an object, by successive comparative features, into classes with increasingly fewer members. Salience of a feature, therefore, should increase inversely with the number of members of a class into which it places an object; $A \cap B$ increases and may be thought of as an expression of diagnosticity. A comparative process that does not maximize diagnosticity or exploit features that do so will have low forensic utility.

The Comparative Method Within Forensic Science

The comparative method involves the aligning of the relational structures between one or more targets (items of questioned source; Qs) and one or more sources (items of known

provenance or source; Ks). This alignment, to work as a method, has three constraints or requirements:

- The alignment has to be *structurally consistent*, that is, it has to observe a one-to-one correspondence between the comparators in an argumentative structure that is the same between the comparisons (*parallel connectivity*). One point of comparison can be aligned with at most one other point of comparison in the target or source. Similarly, matching relationships must have matching arguments to support them (the reason for the proposed relationship cannot be based on an unrelated argument).
- The comparison has to involve *common relations* but does not have to involve common object descriptions. All the evidence that came from the crime scene, for example, need not have originated from only one source.
- Finally, comparisons are not made merely between the objects at hand but also include all of the higher order 'constraining relations' that they may share (*systematicity*). In biology, this would relate to the evolutionary and genetic connections; for manufactured materials, this would be the design factors and the supply chain of raw materials and intermediate processes that lead to a finished consumer good. The deeper the relational history, the more higher order classes that two objects share, the stronger the relationship they share, and, therefore, the greater is the chance of a shared origin. This obviates the significance of coincidental matches between otherwise similar but unrelated objects: A series of coincidences between two objects are not a salient relationship, no matter how many of them exist. Type I and type II errors stem from these coincidences.

A comparison results in a type of cross-mapping of analogous traits or phenomena that have differential relational roles in two situations (e.g., victim's clothing and crime scene). A systematic mapping between source and target is a natural method for differentiating potentially ambiguous relationships. This relates to the classification of the target and source, the identification of traits or features each has that place them in one or more sets (classes) of items. The cross-mapping is of these traits within a class. Once a source has been aligned to a target, *candidate inferences*, based on the source, can be projected onto the target, such as a shared source or history. A handgun with blood on it, for example, can be compared to a bullet removed from a victim (through test firings of similar ammunition) and determined to have been the source (to some degree of certainty) of the bullet while the blood can be tested through DNA typing with the victim's known sample and be shown to have the victim as its source (again, to some degree of certainty); the fact that the victim's blood is on the handgun indicates a shared history of occurrence (lateral contemporaneity).

Comparison is selective. The requirement of systematicity is predicated on the idea that classes or sets are flexible and hierarchical. Higher order connections predict lower order relations, and commonalities that are not a part of the aligned system of relationships are considered inconsequential: A blue shoe and a blue car have little in common other than the stated color category; likewise, the fact that the source shoe and the target print might have the same kind of outsole

design recedes in importance to the fact that none of the individual traits on the sole appears in the print. Differences that are connected to the hierarchical system of relatedness are called *alignable differences*; those differences with no correspondence at all between the source and the target are called *nonalignable differences*. Alignable differences are more meaningful and salient than nonalignable ones because they exist within the same relationship system making them more relevant to each other. The strange conclusion this observation leads to is that there should be more meaningful differences for comparators that are very similar (*toy train–real train*) than for ones that are less similar (*toy train–toy ship*) because the more similar comparators will have or be derived within more common systems of relationships and will have more alignable differences. As an example, consider all the possible differences for the pair *automobile–truck* and for the pair *duck–baseball*. More alignable differences could be found for the first pair than the second: After a few differences ("You don't play sports with a duck. You don't hunt baseballs."), the list seems pointless because the two are not aligned. The details that could be elicited by comparing *automobile* with *truck*, however, could go on for some time, depending on the level of detail desired. Most sets of comparators in the world are dissimilar (which is why forensic comparisons tend to be stronger in exclusion than inclusion) and this 'non-consideration' heuristic makes sense given humans' cognitive load: 'Intuitively, it is when a pair of items is similar that their differences are likely to be important' (Genter and Markman). Psychological experiments support this statement and it seems to be an integral part of human cognition. Related to this idea is Wittgenstein's proposal 5.5303 in his work *Tractatus logico-philosophicus*: "Roughly speaking, to say of two things that they are identical is nonsense, and to say of one thing that it is identical with itself is to say nothing at all." This points to the need for a statistical evaluation of the *strength* of a comparison, either inclusive or exclusive.

Forensic Classification of Evidence

Glossary

Set Any group of real or imagined objects.

Taxonomy The science of identifying and naming species with the intent of arranging them into a classification.

Taxon (pl. taxa) A group of one or more organisms grouped and ranked according to a set of qualitative and quantitative characteristics; a type of set.

Introduction

Evidence is accidental: Items are transformed into evidence by their involvement in a crime regardless of their source or mode of production. By becoming evidence, their normal meaning is enhanced and expanded. Evidence is initially categorized much as the real world; that is, based on the taxonomy created by manufacturers. Forensic science adds to this classification to further enhance or clarify the meaning of evidence relevant to the goals and procedures of the discipline.

Methods of Classification

Set Theory

Any collection of objects, real or imagined, is a set; set theory is the branch of mathematics that studies these collections. Basic set theory involves categorization and organization of the objects, sometimes using diagrams, and involves elementary operations such as set union and set intersection. Advanced topics, including cardinality, are standard in undergraduate mathematics courses. All classification schemes are based on set theory, to a greater or lesser degree.

The notion of 'set' is undefined; the objects described as constituting a set create the definition. The objects in a set are called the members or elements of that set. Objects belong to a set; sets consist of their members. The members of a set may be real or imagined; they do not need to be present to be a member of that set. Membership criteria for a set should be definite and accountable. The set, 'All people in this room are over 5'5" tall,' is a well-defined, if currently unknown, set – the height of the people in the room would have to be measured to accurately populate the set. If the definition is vague then that collection may not be considered a set. For example, is 'q' the same as 'Q'? If the set is 'The 26 letters of the English alphabet,' then they are the same member; if the set is, 'The 52 upper-case and lower-case letters of the English alphabet,' then they are two separate members.

Sets may be finite or infinite; a set with only one member is called a single or a singleton set. Two sets are identical if and only if they have exactly the same members. The cardinality of a set is the number of members within it, written $|A|$ for set A . A set X is a subset of set Y if and only if every member of X is also a member of Y ; for example, the set of all Philips head screwdrivers is a subset of the set of all screwdrivers. Forensic scientists would term this a 'subclass' but that is a terminological

and not a conceptual difference. Two more concepts are required for the remainder of our discussion. The union of X and Y is a set whose members are only the members of X , Y , or both. Thus, if X were (1, 2, 3) and Y were (2, 3, 4) then the union of X and Y , written $X \cup Y$, would contain (1, 2, 3, 4). Finally, the intersection of two sets contains only the members of both X and Y . In the previous example, the intersection of X and Y would be (2, 3), written $X \cap Y$.

Taxonomy

Natural items, such as animals, plants, or minerals, often occur as evidence. These items are classified according to schemes used in other sciences such as biology, botany, or geology. It is incumbent on the forensic scientist to be knowledgeable about the classification of naturally occurring items.

In biology, taxonomy, the practice and science of classification, refers to a formalized system for ordering and grouping things, typically living things using the Linnaean method. The taxa (the units of a taxonomic system; singular 'taxon') are sufficiently fixed so as to provide a structure for classifying living things. Taxa are arranged typically in a hierarchical structure to show their relatedness (a phylogeny). In such a hierarchical relationship, the subtype has by definition the same constraints as the supertype plus one or more additional constraints. For example, 'macaque' is a subtype of 'monkey,' so any macaque is also a monkey, but not every monkey is a macaque, and an animal needs to satisfy more constraints to be a macaque than to be a monkey. In the Linnaean method of classification, the scientific name of each species is formed by the combination of two words, the genus name ('generic' name), which is always capitalized, and a second word identifying the species within that genus. Species names (genus species) are either italicized or underlined, for example, *Homo sapiens* (humans), *Sus scrofa* (pigs), *Canis familiaris* (domesticated dogs), and *Rattus rattus* (rats).

The term 'systematics' is sometimes used synonymously with 'taxonomy' and may be confused with 'scientific classification.' However, taxonomy is properly the describing, identifying, classifying, and naming of organisms, while 'classification' is focused on placing organisms within groups that show their relationships to other organisms. Systematics alone deals specifically with relationships through time, requiring recognition of the fossil record when dealing with the systematics of organisms. Systematics uses taxonomy as a primary tool in understanding organisms, as nothing about the

organism's relationships with other living things can be understood without it first being properly studied and described in sufficient detail to identify and classify it correctly.

In geology, rocks are generally classified based on their chemical and mineral composition, the process by which they were formed, and by the texture of their particles. Rocks are classified as igneous (formed by cooled molten magma), sedimentary (formed by deposition and compaction of materials), or metamorphic (formed through intense changes in pressure and temperature). These three classes of rocks are further subdivided into many other sets; often, the categories' definitions are not rigid and the qualities of a rock may grade it from one class to another. The terminology of rocks and minerals, rather than describing a state, describes identifiable points along a gradient.

Manufacturing

Manufactured evidence is initially categorized by the in-house or market-specific system created by one or more manufacturers. Manufacturers of economic goods create their classifications through product identity or analytical methods. Set methods of production ensure a quality product fit for purpose and sale; the classification is based on the markets involved, the orientation of the company production methods, and the supply chain. Explicit rules exist on categories recognized by manufacturers and consumers, as either models or brands. Materials flow downstream, from raw material sources through to a manufacturing level. Raw materials are transformed into intermediate products, also referred to as components or parts. These are assembled on the next level to form products. The products are shipped to distribution centers and from there on to retailers and customers.

Forensic Approaches to Classification

The supply network of raw materials, intermediate steps, production methods, intended consumer end use, and actual end use all contribute to the characteristics available for forensic taxonomic classification. While the forensic taxonomies are unique to that discipline, they are based on the production taxonomies used in manufacturing. These characteristics form the basis for statements of significance, that is, the relative abundance or rarity of any one particular item in a criminal context. Some objects are common but have a short-entrance horizon (e.g., iPods), but are essentially identical at the outset while others are common with long-entrance horizons (denim blue jeans), but have a high variance (regular, stone washed, acid washed, etc.). It is in the best interest of forensic scientists to understand the fundamental manufacturing processes of the items that routinely become evidence. This understanding can form the basis for statistical significance statements in courts and may provide the foundations for a more quantitative approach to testimony.

Forensic analytical methods create augmented taxonomies because the discipline uses different sets of methods and forensic scientists have different goals. Their taxonomies are based on manufactured traits, but also aftermarket qualities, and intended end use, but also 'as used.' The 'as used' traits are those imparted to the item after purchase through either

normal or criminal use. Forensic science has developed a set of rules through which the taxonomies are explicated. For example, forensic scientists are interested in the size, shape, and distribution of delustrants, microscopic grains of rutile titanium dioxide incorporated into a fiber to reduce its luster. The manufacturer has included delustrant in the fiber at a certain rate and percentage with no concern for shape or distribution (but size may be relevant). The forensic science taxonomy is based on manufacturing taxonomy but is extended by incidental characteristics that help us distinguish otherwise similar objects.

Natural, manufacturing, and forensic classifications lead to evidentiary significance because they break the world down into intelligible classes of objects related to criminal acts. Forensic science has developed an enhanced appreciation for discernment between otherwise similar objects but has yet to explicate these hierarchies to their benefit.

Class Level Information

Identification is the examination of the chemical and physical properties of an object and using them to categorize it as a member of a set. What the object is made of, its color, mass, size, and many other characteristics are used to identify an object and help refine that object's identity. Analyzing a white powder and concluding that it is cocaine is an example of identification; determining that a small translucent chip is bottle glass or yellow fibrous material and determining that they are dog hairs are also examples of identification. Most identifications are inherently hierarchical, such as classification systems themselves: In the last example, the fibrous nature of the objects restricts the following possible categories:

- Hairs
- Animal hairs
- Guard hairs
- Dog hairs
- German shepherd hairs

As the process of identification of evidence becomes more specific, it permits the analyst to classify the evidence into successively smaller classes of objects. It may not be necessary to classify the evidence beyond dog hairs if human hairs are being looked for. Multiple items can be classified differently, depending on what questions are asked. For example, the objects in [Figure 1](#) could be classified into 'fruit' and 'nonfruit,' 'sports related' and 'nonsports related,' or 'organic' and 'inorganic.'

Sharing a class identity may indicate two objects that come from a common source. Because forensic science reveals and describes the relationships among people, places, and things involved in criminal activities, this commonality of relationship may be critical to a successful investigation. Commonality can show interactions, limitations in points of origin, and increased significance of relationships. What is meant by a 'common source' depends on the material in question, the mode of production, and the specificity of the examinations used to classify the object. For example, the 'common source' for an automotive paint chip could be the following:

Figure 1 A range of objects may be classified in a variety of ways, depending on the question being asked. For example, given the objects in this figure, the sets would differ if the question was, "What's edible?" rather than, "What is sporting equipment?"

- the manufacturer (to distinguish it from other similar paints),
- the factory (to determine where it was made),
- the batch or lot of production (to distinguish it from other batches at the same factory),
- all the vehicles painted with that color paint, or
- the vehicle painted with that color paint involved in the crime in question?

All of these options, and they are not exhaustive, could be the goal in an investigation of determining whether two objects had a 'common source.'

Uniqueness and Individualization

If an object can be classified into a set with only one member (itself), it can be said to be unique. An individualized object is associated with one, and only one, source: It is unique. Uniqueness is based on two assumptions. The first assumption is that all things are unique in space and, thus, their properties are nonoverlapping. The assumption of uniqueness of space is considered axiomatic and, therefore, an inherently non-provable proposition for numerous reasons. The population size of 'all things that might be evidence' is simply too large to account. In addition, conclusive evidence is not readily available in typical forensic investigations. Because of this, as Schum notes, statistics are required:

Such evidence, if it existed, would make necessary a particular hypothesis or possible conclusion being entertained. In lieu of such perfection, we often make use of masses of inconclusive evidence having additional properties: The evidence is incomplete on matters relevant to our conclusions, and it comes to us from sources (including our own observations) that are, for various reasons, not completely credible. Thus, inferences from such evidence can only be probabilistic in nature (Schum, 1994, p. 2).

A statistical analysis is therefore warranted when uncertainty, of either accounting or veracity, exists. If an absolutely certain answer to a problem could be reached, statistical methods would not be required. Most evidence exists at the class level, and although each item involved in a crime is considered unique, it still belongs to a larger class. In reality,

the majority of forensic science works at a class level of resolution. Indeed, even DNA, the argued 'gold standard' of forensic science, operates with classes and statistics.

It has been argued that the concept of uniqueness is necessary but not sufficient to support claims of individualization. If it is accepted that uniqueness is axiomatic, then

What matters is whether we have analytical tools necessary to discern the characteristics that *distinguish* one object from all others or, in the forensic context, distinguish *traces* made by each object from traces made by every other object ... Every object is presumably unique at the scale of manufacture. The question is whether objects are distinguishable at the scale of detection. Since all objects in the universe are in some respects 'the same' and in other respects 'different' from all other objects in the universe, according to Wittgenstein, what really matters is not uniqueness but rather what rules we articulate by which we will make determinations of 'sameness' and 'difference' (Cole, 2009, pp. 242–243).

Although things may be numerically unique at the point of *production*, this does not help to distinguish between otherwise similar objects at the point of *detection* or *interpretation*. This is where forensic science adds value to the investigative and legal processes.

Relationships and Context

The relationships between the people, places, and things involved in crimes are central to deciding what items to examine and how to interpret the results. For example, if a sexual assault occurs and the perpetrator and victim are strangers, more evidence may be relevant than if they live together or are sexual partners. Strangers are not expected to have ever met previously and, therefore, would have not transferred evidence before the crime. People who live together would have some opportunities to transfer certain types of evidence (e.g., head hairs and carpet fibers from the living room) but not others (semen or vaginal secretions). Spouses or sexual partners, being the most intimate relationship of the three examples, would share a good deal of more information (Figure 2).

Stranger-on-stranger crimes beg the question of coincidental associations, that is, two things that previously have never been in contact with each other have items on them, which are

Figure 2 The relationships between suspect, victim, and scene influence what evidence is collected, and what its significance is.

analytically indistinguishable at a certain class level. Attorneys in cross examination may ask, 'Yes, but could not [insert evidence type here] really have come from anywhere? Are not [generic class level evidence] very common?' It has been proven for a wide variety of evidence that coincidental matches are extremely rare. The enormous variety of mass-produced goods, consumer choices, economic factors, biological and natural diversity, and other traits create a nearly infinite combination of comparable characteristics for the items involved in any one situation.

FOUNDATIONS/FUNDAMENTALS

Measurement Uncertainty

Ted Vosk, Criminal Defense Law Firm, Kirkland, WA, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Bias The quantitative characterization of systematic error.

Combined uncertainty The standard uncertainty associated with the final measurement result determined by ‘adding’ up the standard uncertainties associated with each of the individual sources of uncertainty.

Coverage factor A positive, real number that when multiplied by a measurement’s combined uncertainty yields the expanded uncertainty. The coverage factor determines the level of confidence associated with a coverage interval.

Coverage interval An interval about the best estimate of a measurand’s ‘true’ value that will contain those values believed to be attributable to the measurand with a specified level of confidence.

Expanded uncertainty Measure of uncertainty obtained by multiplying a measurement’s combined uncertainty by a coverage factor. It defines the half width of a coverage interval.

Level of confidence The probability, defined as a degree of belief, that the ‘true’ value of a measurand lies within the range defined by a coverage interval.

Measurand The quantity whose value is sought to be determined by a measurement.

Measurement function A function that describes the relationship between the measurand value and those quantities required to determine it.

Quantity Physical properties subject to measurement, such as length, time, weight, and concentration.

Random error The inherent unpredictable fluctuation in measured values under fixed conditions.

Sensitivity coefficients The partial derivatives of a measurement function that describe how the measurand’s value varies with changes in the values of the input quantities.

Standard uncertainty Measurement uncertainty expressed as the standard deviation of a frequency or belief based probability distribution.

Systematic error The tendency of a set of measurements to consistently (on average) underestimate or overestimate the ‘true’ value of a measurand by a given value or percentage.

Uncertainty The quantitative characterization of the dispersion of values that, based on one’s universe of information concerning a measurement, are believed to be reasonably attributable to a measurand.

Nomenclature

b_{ias}	Bia	y	Measured value
$\bar{y}_c$	Bias corrected mean measured value	$Y_{99\%}$	Measurand value with 99% level of confidence
Y_b	Best estimate of ‘true’ measurand value	ϵ_{ran}	Random error
μ_c	Combined uncertainty	μ_r	Relative standard uncertainty
k	Coverage factor	$\partial f/\partial x_i$	Sensitivity coefficients
U	Expanded uncertainty	σ	Standard deviation
X	Input quantities	μ	Standard uncertainty
ϵ_m	Maximum total error	ϵ_{sys}	Systematic error
$\bar{y}$	Mean measured value	Y	‘True’ measurand value
$f(X_1, X_2, \dots, X_N)$	Measurement function	$\boxplus$	Unspecified method for combining ϵ_{sys} and ϵ_{ran}
ϵ	Measurement error		

Measurement

Measurement constitutes a specific category of scientific investigation. It is an empirical process whereby a researcher seeks to determine the numerical magnitude attributable to some

physical/phenomenological quantity of interest referred to as the ‘measurand.’ Many naively consider measurement to be a mechanical process whereby the quantity of interest is sensed/probed by a measuring instrument yielding directly the value attributable to the measurand. This mechanical

activity is simply one step in the overall measurement process, however. Alone, it does not tell us what we want to know about the value(s) attributable to a measurand. Rather than a passively mechanical process of probing and discovery, measurement is more completely understood as an empirically grounded, information-based inference requiring active input from the researcher before any value can be attributed to a measurand. Measurement uncertainty identifies in an explicit, quantitatively rigorous manner the limitations governing the rational inferences that can be made concerning the value(s) attributable to a measurand based on the results of measurement.

Measurement to Meaning

Measurement Error and Error Analysis

What does a measurement result mean? In other words, given a measured value y , what value(s) can actually be attributed to a measurand. Lay people often interpret the value reported by a measurement as representing the singular 'true' value attributable to a measurand (Figure 1):

Figure 1 Measurement as singular 'True' value.

Figure 2 Measurement in reality inherent error.

$$Y = y \quad [1]$$

Science has long realized, however, that 'error' is an inherent characteristic of measurement distinguishing measured values from the 'true' quantity values sought to be determined (Figure 2).

Error analysis is the traditional approach to the interpretation of measurement results. It is based on the premise that if the error associated with a measurement can be determined then a measurand's 'true' value can also be determined:

$$Y = y - \varepsilon \quad [2]$$

There are two types of errors associated with every measurement: random and systematic. Systematic error is the tendency of a method/instrument to yield values that are consistently (on average) artificially inflated or depressed with respect to the 'true' values of the quantities being measured. It is quantitatively characterized as bias (Figure 3).

The identification of systematic error can be one of the most difficult aspects of the measurement process. The reason is that if one is measuring an unknown quantity, the measured values themselves provide no basis for concluding that they are systematically offset from the measurand's 'true' value. Thus, one can never know whether all systematic errors associated with a measurement have been identified. Some sources of systematic error can be identified and quantified through measurement of reference materials. Even when rigorously determined in this manner, however, the magnitude of the bias can never be exactly known.

Random error is the unpredictable/random fluctuation in measured values under fixed conditions. It introduces inherent variability into the measurement process placing a fundamental limitation on the repeatability of measured results. For many common situations, the random variation in a measurement's results can be approximately characterized by a Gaussian (normal) distribution (Figure 4).

Random error is quantitatively characterized by a set of measurement's standard deviation:

Figure 3 Systematic error and bias.

Figure 4 Random error and variability.

Figure 6 Error analysis estimate as close as possible.

Figure 5 Measurement error.

$$\sigma_y = \sqrt{\frac{\sum_{i=1}^n (y_i - \bar{y})^2}{n-1}} \quad [3]$$

The standard deviation provides a measure of the variability of individually measured values about their mean. If there is significant variability, the standard deviation will be large. If variability is slight, the standard deviation will be small.

Systematic and random errors describe aspects of the *physical state of a measurement*. It is not always clear whether an error should be categorized as systematic or random, and the determination may be context dependent. Taken together, they constitute what is formally known as ‘measurement error’ (Figure 5).

The total error associated with a measurement can never be absolutely determined, that is, it is unknowable. As a result, error analysis can never supply a measurand’s ‘true’ value. Instead, the goal of error analysis is to identify, minimize, and eliminate *as best as possible* all identifiable sources of error so as to provide an estimate of a measurand’s value that is *as close as possible* to its ‘true’ value (Figure 6).

This requires some method for combining systematic and random components of error to obtain a characterization of a measurement’s total error:

$$\varepsilon = \varepsilon_{\text{sys}} \oplus \varepsilon_{\text{ran}} \quad [4]$$

To understand where this leads, one must have an idea of the mathematical underpinnings of error analysis. Error analysis is ground in frequentist statistical theory. Frequentist theory defines probability in terms of relative frequency of occurrence. This means that the probability that a particular condition will be found to exist is determined by how frequently it occurs within the universe of all possible events. Although these probabilities can seldom be known because the universe of all possible events can seldom be completely known, they can be ‘objectively’ estimated as the relative frequency of occurrence over sample data sets. What is critical is that in error analysis, the estimation of probabilities is ‘objectively’ based solely on statistical sampling according to the frequentist paradigm.

The analysis of random error fits well within the frequentist paradigm. On the other hand, except in limited circumstances, the evaluation of systematic error does not. Because systematic and random errors are different in nature, each requires distinct treatment. There is no rigorously justifiable manner within the frequentist paradigm by which systematic and random errors can be combined to yield a statistically meaningful estimate of a measurement’s total error.

Due to the frequentist underpinnings of error analysis, the best it can provide is an upper limit on a measurement’s total error. This bounded error is often expressed as some linear combination of the bias and standard deviation associated with a measurement:

$$\varepsilon_m = b_{\text{ias}} + 3\sigma \quad [5]$$

This places a bound on the maximum separation expected between a measured and ‘true’ value. It does not, however, denote how close together the two values are *actually* expected to lie. In other words, it tells us the worst a measurement result could be without any indication of how good it actually is. Moreover, the meaning of this bounded error is vague, as it

fails to tell us how probable it is that a measured value lies within the prescribed range of the measurand's 'true' value. Given a measured value y , the best error analysis provides is an incompletely defined estimate of the maximum separation between a measured value and a 'true' value. It cannot tell us the values that are likely to be attributable to the measurand given a particular measured value.

The Meaning of Meaning

A significant epistemological question surrounds any scientific proposition: Is a scientific proposition intended to describe some physical state of the universe itself or simply to describe our state of knowledge about such a physical state? If it is the former, the direct object of the proposition is an external fully independent reality. If it is the latter, the direct object of the proposition is an internal cognitive position that is information dependent. Many claim that if scientific propositions are to be objectively meaningful, they must fall into the first category. Others counter that regardless of the objective content of scientific propositions, they necessarily reside in the second category as all we can ever actually claim to know is our internal cognitive state, not some independent external reality.

Although seemingly esoteric, the position adopted can have practical implications. It may change not only the interpretation of scientific statements but also the manner in which they can be investigated. And so it is with scientific measurement. When a measurement result is reported, is it to be interpreted as a statement about the physical state of a measurand? Or, is it simply an expression of our state of knowledge about the measurand's physical state? And what are the practical implications of the choice made?

Measurement error is an aspect of the *physical state* of a measurement. It is related to a measurand through error analysis that purports to convey the bounds of its actual *physical state* through the determination of a bounded error. Where a precise estimate of a measurand's actual value is not critical, the bounded error may provide a result with sufficient meaning to be useful. Where a measurand's actual value is important, however, this level of meaning may be inadequate. If possible, one would like to understand the meaning of a measured value in terms of how it maps into those values that are *likely* to be attributable to the measurand.

Measurement Uncertainty

The New Paradigm

Measurement uncertainty addresses the shortcomings of error analysis by fundamentally redefining the way measurement is interpreted and providing a quantitative metric for mapping measured values into those believed to be reasonably attributable to a measurand. In this new paradigm, error is replaced as the focus of analysis by a new entity: uncertainty. This is not a matter of mere semantics. Uncertainty and error are completely distinct concepts. While measurement error concerns the actual *physical state* of a measurand, measurement uncertainty relates to the *state of knowledge about* the measurand.

Figure 7 Measurement as packet of values.

This does not mean that those phenomena formerly understood as systematic and random errors are ignored. To the contrary, they are fully encompassed within the uncertainty framework. What they represent, however, has been reconceptualized to overcome the limitations inherent in frequentist philosophy. Central to the uncertainty paradigm is the alternative Bayesian notion of probability as a degree of belief. That is, probability is defined by how strongly one believes a given proposition. This formulation permits consideration of information about a measurand beyond that cognizable in frequentist theory and provides a common basis for its analysis whether statistically or nonstatistically based.

In the uncertainty paradigm, as in error analysis, a measurand's 'true' value is unknowable. However, this is not due to the physical phenomenon of irreducible error, but due to the impossibility of our ever possessing perfect knowledge concerning a measurand's state. Uncertainty focuses on this limitation interpreting a measurement result as a probability distribution that characterizes one's state of knowledge about a measurand's value. While measurement error as a physical phenomenon is as unknowable as a measurand's 'true' value, the characterization of a result as a probability distribution in this manner permits a result's uncertainty to be rigorously determined.

When a measurement is performed, it always takes place against a backdrop of existing information about the measurement to be made and the measurand itself. Some of this information may be in the form of statistically obtained data, while some may be based on other sources such as general knowledge of the behavior and properties of relevant materials, methods, and instruments. When a measurement is performed, the discrete value obtained adds to our universe of information and updates our state of knowledge concerning the measurand. Because our information is necessarily incomplete, our knowledge concerning the measurand remains fuzzy. Given the information possessed, the discrete value obtained represents a packet of values dispersed about the measured result, all of which are believed to be attributable to the measurand with relative degrees of conviction (Figure 7).

It is the identification of probabilities as degrees of belief that transforms this packet of values into a probability

Figure 8 Measurement as probability distribution.

Figure 9 Probability = ratio of areas under curve.

distribution. In this context, the meaning of a measured value corresponds to a probability distribution characterizing the relative likelihood of the values believed to be attributable to a measurand based on the totality of currently available information (Figure 8).

This distribution completely specifies our state of knowledge concerning the values attributable to a measurand. Moreover, it delineates in a mathematically rigorous manner how a measured value, y , maps into those values believed to be attributable to a measurand. By doing so, it also determines the inferences that can be made concerning a measurand's value based on the values measured.

As an example, given a measured value, the distribution permits one to determine the probability that a measurand's value lies within any given range of values. In this context, one can think of the probability associated with the distribution as being equal to the area under the curve representing it. The probability that a measurand's value lies within a specified range is given by the proportion of the area under the curve spanning the range in question to the total area under the curve (Figure 9).

Given a measured value, y , the question of what values can *reasonably* be attributed to a measurand involves two competing considerations. First, we want to exclude values that, although possible, are highly improbable. Second, we need to include enough values so that there is a significant probability that the measurand's value is actually among those considered. The measurement's probability distribution provides a conceptually straightforward way of accomplishing this. Simply slice off the tails of the distribution while including enough of its

Figure 10 Values reasonably attributable to measurand.

Figure 11 Expanded uncertainty.

middle so that the area of the remaining region represents a significant probability that the measurand's value lies within it (Figure 10).

From this, we can obtain a range of values reasonably attributable to a measurand, along with an associated probability that the value of the measurand lies within it. This defines the uncertainty of a measurement. Measurement uncertainty is the quantitative characterization of the dispersion of values that, based on the universe of information concerning a measurement, are believed to be *reasonably* attributable to a measurand. The half-width of this range of values is known as a result's expanded uncertainty, U (Figure 11).

The expanded uncertainty defines what is known as a 'coverage interval' about a measured value. The coverage interval conveys the set of quantity values reasonably attributed to the measurand along with the specific probability that its 'true' value actually lies within this range. The probability is referred to as the interval's associated 'level of confidence.' Coverage intervals having an associated level of confidence between 95% and 99.7% are typically selected (Figure 12):

Figure 12 Coverage interval.

Figure 13 Interpretation of a confidence interval.

$$\text{Coverage interval} \\ y - U < Y_{99\%} < y + U$$

[6]

Coverage Interval Versus Confidence Interval

Coverage intervals and confidence intervals are distinct tools and should not be confused. A coverage interval is a metrological concept based on Bayesian analysis. In this framework, parameters of interest can be treated as random variables so that they can be the subject of probabilistic statements without logical inconsistency. The level of confidence associated with a coverage interval refers to the probability, understood as a degree of belief, that a measurand's value lies within the interval.

A confidence interval is a statistical concept based on frequentist methodology. In this framework, the stochastic nature of the investigation lies entirely in the sampling process, not the parameter value. Accordingly, the level of confidence associated with a confidence interval does not associate a probability with the measurand value. Rather, its object is the interval itself. If one were to conduct multiple sets of measurements and generate a confidence interval for each set, the level of confidence tells you the proportion of these intervals that would be expected to cover/overlap a measurand's value (Figure 13).

There are two types of uncertainties: type A and type B. Unlike the two types of errors, type A and type B uncertainties are not distinguished by the nature of their source. Instead, they are defined by the manner in which they are determined. Type A uncertainty refers to the uncertainty that has been determined by statistical (frequentist) methods utilizing observed frequency distributions. Type B uncertainty refers to the uncertainty that has been determined by nonstatistical means relying on knowledge, experience, and judgment to create belief-based *a priori* distributions.

Type A evaluations are often referred to as 'objective' and type B as 'subjective.' However, this does not mean that type B evaluations are any less real or valid than type A. Both evaluations rely on accepted notions of probability. Nor is one approach necessarily superior to the other. Whether type A or type B analysis yields better results is context dependent.

Regardless of the approach employed to determine them, a foundational tenant of this paradigm is that the uncertainties themselves do not differ in nature. Once determined, all distributions are interpreted in the Bayesian manner, representing models of our state of knowledge quantified according to degree of belief. This permits type A and type B uncertainties to be treated on equal footing as standard deviations of the distributions they are based on, providing rigorous justification for their combination into a 'combined uncertainty' using traditional methods of analysis.

The importance of this lies in the fact that a measurement's uncertainty is usually made up of the combination of uncertainties from several distinct sources. To understand the significance, recall the inability of error analysis to combine systematic and random errors in a rigorously justifiable manner to determine a measurement's total error. To avoid confusion, in the context of uncertainty, systematic errors are referred to as 'systematic effects.' For pedagogical purposes, systematic effects were not included in the above discussion. Nonetheless, the determination of uncertainty assumes that every measurement has been corrected for significant systematic effects.

What the uncertainty paradigm permits us to do, regardless of the nature of a systematic effect or how it has been quantified, is to treat it as a probability distribution. When this is done, the distribution's expectation yields the required systematic correction (hereinafter referred to as bias) and its standard deviation characterizes the uncertainty associated with the bias. Treated in this manner, systematic effects and their associated uncertainties are placed on equal footing with measured values and their associated uncertainties, so that those phenomena formerly understood as systematic and random errors can now be combined in a logically consistent and rigorously justifiable manner. In general, the evaluation of the uncertainty arising from systematic effects may be either type A or type B.

Returning to the above discussion, it can now be seen that the uncertainty paradigm naturally incorporates systematic effects into the mapping of measured values to those believed to be attributable to a measurand (Figure 14).

The correction shifts the position of the probability distribution along the axis of values while the uncertainty associated with the correction will modify the shape of the distribution. As would be expected, this will shift the coverage interval in the direction of the correction as well.

Figure 14 Mapping measurement to 'reality'.

Something that must be considered at this point is that given the inherent variability of measured values, it is seldom acceptable to base the determination of a measurand's value on a single measurement. Good practice requires acquisition of multiple measured values combined to determine their mean. The *best estimate* of a measurand's 'true' value is then given by the *bias corrected mean* of the measured values:

$$\begin{aligned} \text{Best estimate} &= \text{bias corrected mean} \\ Y_b &= \bar{y}_c \end{aligned} \quad [7]$$

It is a fundamental principle of measurement that where the actual value of a measurand is important, a result is not complete and cannot be properly interpreted unless it has been corrected for bias and is accompanied by a quantitative statement of its uncertainty. Accordingly, a complete measurement result consists of the best estimate of the measurand's 'true' value accompanied by its uncertainty:

$$\begin{aligned} \text{Measurement result} &= \text{best estimate} \pm \text{uncertainty} \\ Y_{99\%} &= Y_b \pm U \end{aligned} \quad [8]$$

$$\begin{aligned} \text{Coverage interval} \\ Y_b - U < Y_{99\%} < Y_b + U \end{aligned} \quad [9]$$

Measurement Uncertainty: A Forensic Example

The value of a measurand can be critical to the determination of certain criminal matters. For example, some states define the offense of driving under the influence of alcohol (DUI) by an individual's 'true' breath alcohol concentration (BrAC). The measurement of BrAC, like any other scientific measurement, is accompanied by uncertainty. Thus, by themselves, the values reported by a breath test machine tell us little about an individual's 'true' BrAC and whether they have actually committed a crime. Consider tests administered to two different individuals on different instruments in a state where DUI is defined by a BrAC of 0.08 g/210 L (Figures 15 and 16).

Each test reports identical BrAC values in excess of the state's *per se* limit with a mean value of 0.0825 g/210 L. Without more, these 'breath test tickets' clearly seem to indicate that the BrACs in question exceed the legal limit. Moreover, given

Figure 17 BrAC test 1.

that the external standard readings are both reading true, there is actually no way to distinguish between these two tests.

The two tests' uncertainties reveal a different picture though. Despite identically measured values, the uncertainty of each, expressed as coverage intervals, is different (Figures 17 and 18).

Clearly, the computed uncertainty associated with test 1 is greater than that associated with test 2. Moreover, further examination reveals that the likelihood that each individual's BrAC is actually less than 0.08 g/210 L is nearly 20% and 10% for tests 1 and 2, respectively (Figures 19 and 20).

Thus, not only do these 'identical' tests not have identical meanings, but each represents a sizeable likelihood in the context of reasonable doubt that the BrACs in question are less than the relevant limit. Proper interpretation of these results clearly requires knowledge of their uncertainty.

Determining Measurement Uncertainty

There are several different methods for determining a measurement's uncertainty. The first step in each is to identify

Figure 18 BrAC test 2.

Figure 19 BrAC test 1.

Figure 20 BrAC test 2.

and quantify all systematic effects and appropriately correct for each.

Figure 21 Cause and effect diagram.

The second step is typically the identification of relevant sources of uncertainty. A common way to document these is through a cause and effect diagram, which depicts each source of uncertainty and their relationship to each other and the final result (Figure 21).

When all the quantities on which a measured value depends can be varied simultaneously, a result's uncertainty can be determined, directly using statistical methods. Except for simple measurements, however, this approach is typically not practical.

Generally, then, the next step is to determine the magnitude of each of the relevant uncertainties. Each is quantified as a standard deviation and referred to as a 'standard uncertainty:'

$$\text{Standard uncertainty} \quad \mu \equiv \sigma \quad [10]$$

The relative standard uncertainty is the ratio of the standard uncertainty to the best estimate of the measurand value. It can be useful when combining or comparing uncertainties of separate measurements:

$$\text{Relative standard uncertainty} \quad \mu_{r_y} = \frac{\mu_y}{|Y_b|} \quad [11]$$

For some measurements, each source of uncertainty may be associated with the measurement as a whole and manifest itself independently as a direct effect on the final result. Such is the case with direct measurements. In these circumstances, a result's 'combined uncertainty,' μ_c , is given by the root-sum-square (rss) of the standard uncertainties:

$$\mu_c = \sqrt{\sum_{i=1}^n \mu_i^2} \quad [12]$$

Most measurements are indirect in nature, determining a measurand's value through its relationship to other measured quantities. The most common method of determining uncertainty in these circumstances is discussed in the 'Guide to the Expression of Uncertainty in Measurement' (the 'GUM'). Application of the GUM requires that a measurement be modeled as a mathematical function, referred to as the Measurement Function:

$$\text{Measurement function} \quad Y = f(X_1, X_2, \dots, X_N) \quad [13]$$

This function describes the relationship between the measurand value and those quantities required to determine it. For

example, if the measurand is the volume of a cylinder, the measurement function might be given as

$$V(r, h) = \pi r^2 h \quad [14]$$

The combined uncertainty of the measurand is determined by 'adding' up the individual standard uncertainties using the method of 'Propagation of Uncertainty':

$$\mu_c = \sqrt{\sum_{i=1}^N \left(\frac{\partial f}{\partial x_i} \cdot \mu_{x_i} \right)^2 + 2 \sum_{i=1}^{N-1} \sum_{j=i+1}^N \frac{\partial f}{\partial x_i} \cdot \frac{\partial f}{\partial x_j} \cdot \mu_{x_i x_j}} \quad [15]$$

If each of the input quantities is independent, the expression simplifies to

$$\mu_c = \sqrt{\sum_{i=1}^N \left(\frac{\partial f}{\partial x_i} \cdot \mu_{x_i} \right)^2} \quad [16]$$

For the volume of a cylinder, the combined uncertainty would be given by the expression

$$\mu_{cv} = \sqrt{(2\pi r h \mu_r)^2 + (\pi r^2 \mu_h)^2} \quad [17]$$

Propagation of Uncertainty: Applied to Measurement Functions with Independent Input Quantities

$$1. \text{ Measurement function: } Y = a \cdot X \quad [18]$$

$$Y_b = a \cdot x_b \quad [19]$$

$$\mu_y = a \cdot \mu_x \quad [20]$$

$$2. \text{ Measurement function: } Y = X^n \quad [21]$$

$$Y_b = x_b^n \quad [22]$$

$$\mu_{r_y} = \frac{\mu_y}{|Y_b|} = |n| = \frac{\mu_x}{|x_b|} \quad [23]$$

$$3. \text{ Measurement function: } Y = X - W + \dots + Z \quad [24]$$

$$Y_b = x_b - w_b + \dots + z_b \quad [25]$$

$$\mu_y = \sqrt{\mu_x^2 + \mu_w^2 + \dots + \mu_z^2} \quad [26]$$

$$4. \text{ Measurement function: } Y = \frac{X \times \dots \times W}{Z \times \dots \times Q} \quad [27]$$

$$Y_b = \frac{x_b \times \dots \times w_b}{z_b \times \dots \times q_b} \quad [28]$$

$$\mu_{r_y} = \frac{\mu_y}{|Y_b|} = \sqrt{\left(\frac{\mu_x}{x_b} \right)^2 + \left(\frac{\mu_w}{w_b} \right)^2 + \dots + \left(\frac{\mu_z}{z_b} \right)^2 + \left(\frac{\mu_q}{q_b} \right)^2} \quad [29]$$

The expanded uncertainty is obtained by multiplying the combined uncertainty by a coverage factor, k :

$$\text{Expanded uncertainty} \quad U = k \mu_c \quad [30]$$

The coverage factor determines the coverage interval's level of confidence. It is commonly based on a t -distribution. Where a measurement's degrees of freedom are sufficiently large, the

Figure 22 Coverage factors and levels of confidence: Gaussian distribution.

level of confidence bestowed by a given coverage factor is approximately that associated with a Gaussian distribution (Figure 22).

The coverage factor is typically chosen to yield a level of confidence of 95% or greater. For the volume of a cylinder, the expanded uncertainty yielding a 99% level of confidence would be given by the expression

$$U = 2.576 \sqrt{(2\pi r h \mu_r)^2 + (\pi r^2 \mu_h)^2} \quad [31]$$

For the *GUM* to apply, the distribution characterizing a final result must not depart appreciably from normality. Where this is not the case, or where a measurement function is complicated or unknown, a more general approach to the determination of uncertainty is based on the *propagation of distributions*. Instead of determining the standard uncertainty of each input quantity and combining them, the distributions characterizing the quantity value of each input quantity are directly combined to construct the distribution characterizing our state of knowledge of the measurand's value (Figure 23).

The standard deviation of the final distribution yields a result's standard uncertainty. It should be noted that the resultant distribution and, hence, its uncertainty (coverage interval) need not be symmetric about the mean. The Monte Carlo method, a computer-based iterative simulation process, is an example of this approach.

A final approach to the determination of uncertainty is the top-down method, so called because it focuses on the measurement process as a whole instead of its detailed breakdown into distinct sources of uncertainty. It utilizes overall reproducibility estimates, based on measurement trials, as a direct estimate of the uncertainty associated with a measurement method. This approach is often utilized where a measurement function is complicated or unknown. Although each has its advantages, in certain circumstances, the *GUM* and top-down approaches can be used together to determine the uncertainty of a measurement where desirable.

Figure 23 Propagation of distributions.

Meaning Requires Uncertainty

Scientific measurement provides a powerful tool for investigating physical phenomena. No matter how good a measurement is, we can never know the 'true' value of the quantity of interest. Error analysis focuses on the measurand itself, with the intent of providing a value that is as close as possible to its 'true' value. What it actually provides is an ill-defined upper limit on a measurement's total error, revealing the worst a measured value might be without conveying how good it actually is. Uncertainty analysis focuses on our state of knowledge about a measurand, providing a quantitative mapping of measured values into those values believed to be actually and reasonably attributable to the quantity of interest. This conveys the meaning of a result by rigorously defining and constraining the inferences that can be drawn from it. Accordingly, where the actual value of a measurand is important, a result is not complete and cannot be properly interpreted unless it is accompanied by a quantitative statement of its uncertainty.

Glossary

Denaturing of DNA The process by which double-stranded DNA unwinds and separates into single-stranded strands through the breaking of hydrogen bonds between the bases.

DNA amplification A process called polymerase chain reaction (PCR). A DNA testing procedure that mimics the cell's ability to replicate DNA, essentially copying it a millionfold.

Electrostatic lifting device A device consisting of a high-voltage supply used with a special conductive lifting film to transfer a dry origin footwear impression electrostatically from a surface to a film.

Latent evidence Evidence at a crime scene that cannot be seen with the naked eye. Examples might be a blood stain that was bleached out, semen stains that cannot be seen without special lighting, or a fingerprint that cannot be seen without powdering.

Probative value Evidence which is sufficiently useful to prove something important in a trial.

Trace evidence Evidence such as hairs, fibers, and residue as well as other microscopic evidence that may not be visible to the naked eye.

Introduction

The role of crime scene investigators at major scenes and incidents is to identify and recover physical and trace evidence that has some probative value in the crime. Crime scenes may involve single or multiple locations and these are referred to as the primary and secondary scenes. For example, the primary scene may be where a person has been killed; however, secondary scenes may result when the body has been moved to a different location, and/or the weapon is found at another location. All locations involved form part of the overall crime scene and the evidence collected from each scene helps solve the puzzle piece by piece.

Forensic evidence collected must be relevant to the crime, not be at risk of being misplaced, lost, or tampered with, not be at risk of contamination from other sources, and remain intact throughout the process of collection and analysis. For this reason, the preservation of forensic evidence commences at the time of arrival of the first police responder at the crime scene. At this time, an immediate assessment must be made and action taken to protect any fragile evidence at risk of loss or damage. From this point on, crime scene investigators must be meticulous in their approach to the collection of evidence and maintain an unbroken chain of custody from the time of collection, to the laboratory for analysis, and through to the presentation of the evidence in a court of law.

Scene Examination

Forensic evidence can appear in many forms, including physical, trace, and latent evidence. In the twentieth century, forensic scientist Edmond Locard advanced the theory on which most forensic science is founded today, and that is that 'every contact leaves a trace.' Locard's principle of exchange is based on the theory that any contact made between two objects will result in transfer of material from one to the other. Therefore, using this principle, items of evidence that have probative value can be determined by assessing areas where the offender, victim, and items within the scene have potentially come into contact with one another.

Initial information received upon arrival at the scene and updates from investigating police will help indicate what is, or could be, potential evidence. The following are considered at the scene or during subsequent investigations: the area the offender used to enter and exit the scene; areas within the scene that have been disturbed; anything that the offender has potentially handled or come into contact with; anything that has been left behind by the offender, that is, a weapon.

Successful identification, recovery, and collection of evidence are dependent upon a methodical and diligent approach to scene examinations. The analysis of any evidence should take into consideration the possible destruction of other trace evidence. The development of a crime scene plan ensures that systematic searches are conducted, and appropriate light sources and chemical enhancement techniques are used by applying least destructive to most destructive methodology. Sequencing the order in which the examinations and/or analysis is conducted is paramount to preserving the integrity of all available evidence types.

Evidence Collection

Once all identified evidence has been recorded in situ by way of notes, sketch plans, photography, etc., appropriate techniques are used to collect the evidence. To prevent damage or contamination of the sample, systematic collection/sampling techniques are used. By following a collection sequence, the potential evidence on the item is maximized while providing the highest level of protection to that evidence. For example, a gun used in the commission of a crime would first need to be fingerprinted, then swabbed for DNA, then submitted for test firing. If this sequence is not followed, one or more evidence types would be lost.

Collection techniques are many and varied and include methods such as swabbing, swatching, lifting, vacuum sweeping, picking, and casting. These techniques are selected according to the type of evidence, the substrate the evidence is located upon, and the physical properties of the evidence itself.

For example, swabbing is the preferred sampling method for biological stains, for example, blood, semen, and saliva; however, if a confirmatory test indicates either semen or saliva on an item of clothing, the preferred method of collection is to cut out a swatch of the stained fabric. Trace or contact DNA can be collected using either a swab or a tape lift. Swabbing involves rubbing a moistened swab over the stain, which rehydrates the cells attached to the area, making them easier to retrieve through the rubbing action of the swab. Tape-lifting removes trace or contact DNA from the item using sterile or ultraviolet (UV)-treated sticky tape. Both techniques allow a large surface area to be sampled, which concentrates any DNA present to a smaller, analyzable sample.

Tape lifts may be used to collect not only trace material such as fingerprints and trace DNA but also macroscopic material such as hairs and fibers. The adhesive side of the tape is repeatedly and firmly patted or rolled over the item causing loosely adhering trace evidence to stick to the tape. The collected lifts are placed onto a transparent backing such as clear plastic sheeting or glass slides which protects the evidence against contamination and permits samples to be easily viewed and removed for further examination or comparison. Hand-picking of hairs, fibers, vegetation on clothing, etc. is another acceptable method of recovery using disposable tweezers. Gel lifts are useful for collecting shoeprints in dust. Similarly, electrostatic dust lifting kits are also commonly used for lifting shoe marks off many surfaces.

Vacuuming is another technique used to collect material from inaccessible areas or where there is a large amount of scattered material. There are several different types of vacuum cleaners used for this purpose. One such vacuum cleaner has a one-use only attachment head that the material is collected into. Once collected, the attachment is removed and sealed in an evidence bag and the contents are later examined in the laboratory. Another type of vacuum cleaner has changeable filters; however, the filter and catchment area of the vacuum cleaner must be changed and rigorously cleaned between each vacuuming to avoid contamination. This method of collection should be used subsequent to other collection techniques as it is indiscriminate and may result in the collection of a large amount of extraneous material.

Casting is a technique used for collection of three-dimensional impressions such as shoe marks in soil or a jemmy mark in a doorframe. This technique involves filling of a three-dimensional footwear impression with material such as Dental Stone that sets, capturing the characteristics that were left in that impression by the footwear. Mikrosil is a casting material used to capture three-dimensional tool mark impressions.

When collecting forensic evidence, it is absolutely essential to properly preserve each item so that the evidence on the item is not damaged or degraded in any way, which would limit its potential evidentiary value. For example, all bloodstained clothing items need to be air dried before packaging. When the garment is fully dried, it should be packaged in a paper bag, as paper allows for the circulation of air. If the garment is packaged in plastic, the garment would become moldy which may result in the denaturing of the DNA.

All items of evidence need to be handled with the utmost of care to prevent contamination. Contamination of evidence can occur in many ways such as handling of evidence without gloves and coughing or sneezing near evidence items destined for DNA analysis. Control measures are put in place to minimize potential contamination including the wearing of personal protection equipment (PPE) such as disposable overalls, gloves, masks, overshoes, and goggles. PPE also provides investigators with a means of self-protection from body fluids that may cause hepatitis or human immunodeficiency virus-related diseases. Another control measure is to regularly change disposable gloves between the collection of evidence items which will reduce the potential for cross-contamination from item to item.

Control Samples

When samples are collected from a crime scene, it is also necessary to collect a control sample of the same material. This control sample is a portion of undamaged material from the same general area as where the crime scene sample is collected. A comparative analysis is conducted between the control sample and the crime scene sample which determines the original components of the material allowing for any introduced substances in the crime scene sample to be identified. For example, during arson investigations, control carpet samples are often collected from preserved areas such as underneath wardrobes for comparison against carpet samples collected from suspected areas of fire origin. Once the composition of the carpet samples are established, any flammable liquids that may have been used to accelerate the fire, such as petrol, can be identified.

An infamous forensic case in the 1970s involved the conviction and subsequent exoneration of Edward Charles Splatt for the murder of a woman in her home. Among other trace evidence, fibers were recovered from the bedsheet on the victim's bed. The three fibers collected were gray in color, like those on Splatt's trousers. Years later, a Royal Commission into the case concluded that the fibers found on the bedsheet had been selectively collected to include only gray fibers and were not representative of Splatt's trousers. This evidence, in part, led to the exoneration of Splatt some 13 years later.

This case demonstrates the criticality of collecting a representative sample of all evidence found at a crime scene, just as it is

equally important to collect a control sample that is completely representative of every component it comprises. Materials such as patterned fabrics may appear to be homogeneous in composition but may actually be heterogeneous and contain different colored fibers, or in the case of a blended fabric, different fiber types such as polyester and cotton. It is essential that the complete range of both dyed fibers and fiber types are captured in the control sample to ensure accurate comparison with crime scene samples.

Chain of Custody

Evidence management is critical to the outcome of criminal prosecutions. Chain of custody is the process of validating how any piece of evidence has been gathered, tracked, and protected on its way to a court of law. Proving chain of custody is necessary to affirm that the evidence has not been tampered with, changed, or substituted. It is essential for police, scientists, and other specialists involved in the case, to demonstrate that a chain of custody exists on every occasion the item is transferred from one person to the next to show with absolute confidence that there is no possibility of misidentification or adulteration of the evidence. Should the defense counsel question the chain of custody for any piece of evidence, a documented path of continuity can prove that the item presented at court is in fact the same item collected from the crime scene. Where there is any discrepancy about where an item has gone to or who has had possession of the item throughout the process, the judge may rule that the chain of custody has been broken and the item may not be admitted into evidence.

Chain of custody requires three different questions to be answered to verify the accuracy and reliability of court testimony by police and forensic scientists: First, that the piece of evidence in question is actually what it is reported to be; second, that a continuous trail of possession by each individual handling the item can be demonstrated from the time it was collected until the time it was presented in Court; and third, that each person who had possession of the item can state that it essentially remained in the same condition from the moment he or she received it, to the moment he or she released it.

Key factors in proving a chain of custody need to commence at the crime scene itself. When items of evidence are located at a scene by the crime scene investigator, an identification marker displaying a unique number or letter is placed next to each item of evidence and recorded in situ by way of photographs, notes, and sketch plans. This procedure of marking the items for identification and accurately recording the details of each item is the first step in the chain of custody tracking process.

After the evidence has been recorded, appropriate packaging is essential to preserve the integrity of the evidence. All evidence bags or containers must be sealed with tamper-evident tape and appropriately labeled. Tamper-evident tape is designed to pull apart or shatter when the seal of the packaging is broken and is very difficult, if not impossible, to remove all tell tale signs of this tape from the packaging. If the sealing tape is not tamper-evident tape, a signature and date across the tape and the bag is required as another control measure of tampering. Details of the evidence item and its

collection are recorded on either preprinted label templates on the evidence bags or on adhesive labels, which are affixed to the front of the bag or container. The label information includes the description of the item, the location, date, time of collection, name of the person collecting it, and a unique forensic case number. These labels, whether preprinted templates or affixed as adhesive labels, also have a chain of custody section that must be signed and dated whenever the evidence bag or container is handed by one person to another.

In some jurisdictions, once all the items of evidence have been packaged and sealed, a forensic exhibit list is compiled by the crime scene investigator that comprises an itemized list of all evidence to be handed over to the officer in charge (OIC) of the case. The OIC will sign the bottom of the exhibit list providing continuity that he or she has taken possession of the forensic evidence items.

Once the items of evidence are transported from a crime scene to a police station or laboratory, the chain of custody procedures must be strictly adhered to. Continuity, storage, and security of the evidence are of utmost importance in the chain of custody process. All evidence items must be entered into an exhibit book or electronic case management system and secured in a locked exhibit room while awaiting further analysis. It is imperative that exhibit storage areas have restricted access that is regularly monitored and audited. Access to searching suites, examination areas, and drying cabinets within laboratories often have security controls in place limiting access to authorized personnel only.

When evidence items are removed from exhibit rooms, the items must be either manually signed out of the exhibit book or electronically transferred using a computerized case management system. Electronic transfers can be completed manually on the system or via a bar code label, where the bar code is scanned and movement of the item is confirmed with a personal pin number. This technology has improved the accountability and accuracy of tracking evidence movements within laboratories.

When a sealed evidence bag is opened for further examination or laboratory analysis, the person doing so must sign the chain of custody details that form part of the label. The crime scene investigator or laboratory analyst will thoroughly document their examination or analysis for each evidence item and record any findings or results. Upon completion of the

examination or analysis, the evidence item must be resealed inside the evidence bag or container and the chain of custody details on the label must be updated to reflect that the bag or container has been resealed by that person.

When external laboratories receive evidence for analysis, another unique laboratory number will be allocated, first to track the items through that laboratory system and, second, to ensure that each item of evidence can be identifiable by the laboratory analyst in Court.

By following the chain of custody rule to the letter, the case can proceed with the knowledge and confidence that the movement of all forensic evidence can be precisely tracked from crime scene to courtroom. This rigorous process ensures that forensic evidence critical to the case is admissible into judicial proceedings allowing a judge and jury to impartially reach a fair and just conclusion based on the forensic evidence before them.

Contamination

P Millen, Paul Millen Associates, London, UK

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Blank sample A random sample of unused consumable.

Contamination The (accidental, deliberate, or neglectful) introduction of material into a location which is likely to

undermine the integrity of inferences that may be drawn of any examination or investigation made of it.

Control sample A sample of background material close to the item or material being recovered.

Definition

Contamination is the (accidental, deliberate, or neglectful) introduction of material into a location which is likely to undermine the integrity of inferences that may be drawn of any examination or investigation made of it.

occurring may be disappointing and regrettable even if with better practice it was avoidable. However, identifying contamination and communicating that fact when it has occurred is the higher professional ideal. The discovery and disclosure of this information is wholly professional.

Background

Forensic science evidence is founded on the outcome of contact and transfer of material. Contamination is a natural but unwanted reality. Therefore, contamination by contact of material between objects or places, which one would later want to associate, must be avoided if at all possible. The nature of the evidence type, whether it is a mark, impression, or contact trace will determine the degree of likely transfer and therefore the risk of contamination. The nature of forensic science evidence must also consider not only association and contamination between two specific objects, but also between generic materials of a similar or the same type.

Contamination should be at the forefront of the mind of any person conducting examinations in forensic science. All those involved in the process have a responsibility to identify potential contamination risks, record, and address them. The issue should be considered a threat within the knowledge and remit of investigators as they assess the potential of the investigation. The risk of contamination should be considered an integral part of their scene investigation planning.

Contamination, or the suggestion of it, may undermine any examination and the evidence from material recovered within an investigation. Laboratory-based scientists may have a particular advantage in conducting their examinations within controlled laboratory conditions which are subject to organizational or national protocols. This is not normally necessarily the case with crime scene investigators. They are sometimes faced with multiple challenges: numerous scenes, dealing with victims, suspects which may be time critical.

The avoidance of contamination is paramount. The total elimination of sources contamination is desired but not feasible. Demonstration (by the taking of actions, additional samples, and recording them) is the only safeguard that an examination is safe, or not if that proves to be the case.

Demonstrating that contamination has occurred may be seen by some as professional neglect. That could not be further from the truth. Practice which has led to contamination

Steps to Avoid Contamination

Control of the crime scene is obviously important. This can be done by establishing the boundary of the scene (be it a location, item, or person) and protecting it. The establishment of a cordon at a major crime scene, marking it with incident tape, and protecting it with police officers is common practice. The same principles apply if the examination is that of a person (a suspect, victim, or witness), recovered vehicle, or any other item. The recording of the names of those who enter and leave the defined scene (or comes into contact with it) and at what time, maintains the integrity of the scene management process. The scene or investigation also extends to persons removed from the scene and those who may be potentially connected with it. The availability of trained crime scene investigators to examine such scenes may not always be adequate. It is a long-established principle that all areas such as scene, victim, vehicle, and suspect should be dealt with by separate scene investigators. But at some stage, most often in the laboratory, items will be examined and compared by the same scientist, where systems are also required to ensure that there is no contamination.

Separation (by time, location, and of examiners), does however, have its drawbacks. It discourages or impedes the subconscious and intuitive linking of observations and evidence by investigators, which is an important part of any investigation. The limited availability of suitably experienced personnel may result in the examination of certain areas being delayed or examined in priority order where the risk of contamination remains an issue.

Contamination continues to be a consideration long after the initial scene examinations have been completed. So the packaging and storage of any material collected must be thought through in advance. This is not simply an issue of continuity of exhibits (sometime referred to as the chain of custody) but more importantly integrity of material within the investigation itself. This is particularly so in a protracted enquiry. If further examinations are conducted by the same

person, then the passage of time itself should not be the only separation.

With sound practice it is possible for the same person to examine areas of a crime scene which it may be desired to link. Ultimately, items may be examined by a single scientist within the forensic science laboratory albeit at different times and in different locations within the laboratory. So too in the field then it is necessary to prepare and plan clean and clear areas of separation in time, place, and the equipment used. The ideal conditions we have already established. It is possible to seriously aim to totally eliminate field contamination and be seen to do so to the satisfaction of the courts.

It is necessary to consider the actions of others before the preservation of the scene areas in the event that contamination has already taken place. It is then that the previous actions of the scene examiner, whether they are in relation to that enquiry or not, along with the equipment used and the added safeguard of adequate controls can be developed.

The nature of the crime investigation may often lead to unintended exposure of the various aspects under investigation at an early stage. This can be done by members of the public prior to the arrival of police and possibly by the first officer attending the scene who may be pursuing other areas without full regard for forensic evidence. This is never an insurmountable issue providing that it is immediately identified so that areas that are still relevant may be targeted. The availability of verbal or written statements of those involved must be secured.

Case Example Two youths are seen in a car that has previously been reported stolen after an unsuccessful robbery. Following a car chase, the youths abandon the vehicle. Some considerable distance from the vehicle and following a search of the area, a person matching description of one of the youths is detained following a struggle. The arresting officers take the arrested person to the vehicle and one of the same arresting officers searches it in the arrested person's presence.

The total denial of involvement by the suspect and the absence of other evidence may result in a request for the examination of the vehicle by a crime scene investigator. Clearly, the subject of transfer of trace evidence such as fibers may not be appropriate due to the actions of the unsuspecting officers who arrested and then took the suspect back to the vehicle while it was searched. The search of a vehicle by a first responder normally has the purpose of recovery of property (stolen goods, drugs, or weapons) and is not for contact or trace evidence. When a suspect is arrested from within a vehicle this is common practice. That is not the case here, the suspect was arrested away from the vehicle. The exact action of the arresting officers, what they touched and recovered and any steps they took needs to be known and recorded. The early identification of this problem is paramount. A refusal on the part of the crime scene investigator to conduct a further detailed examination of the vehicle due to possible, previous contamination may also be inappropriate. Any suggestion that the arresting officer had sat or crawled over the seats to search the vehicle would mean that a subsequent examination to locate fibers on the seats from the suspect's clothing would be highly questionable. However, it is still possible for a crime scene investigator to examine the vehicle for material that

could not have been accidentally contaminated. This includes finger marks in particular and marks in general. In the event that those involved may have discarded gloves and masks in the car, consideration may be given to the simultaneous examination of the suspect's hair for fibers by a different crime scene investigator. The persistence of fibers in head hair in numbers beyond those considered by the scientist to be the result of contamination may give the court clear direction. It may be suggested that one fiber could be within the realms of contamination. A large number of fibers in such a specific area (such as the suspect's hair) perhaps would not be. This is a matter of consideration and interpretation by the scientist who later conducts the laboratory examination. The examination of papers in the foot wells of the vehicle may reveal shoe marks in dust. This is a potentially strong form of evidence which it would not be possible to contaminate without the suspect actually sitting in the vehicle.

Contamination is not necessarily the highest priority for first responders, nor should it be. They should not however return to a crime scene with an arrested person whom they may later wish to associate with the scene using forensic science evidence. Arresting officers are rarely if ever in a position to search a suspect or vehicle using anticontamination techniques and clothing available to crime scene investigators and scientists. Once the actions of first responders are known, a detailed examination may reveal potential evidence which is beyond the suggestion and risk contamination.

Choosing Who Should Examine the Scene (Location, Person, or Item)

Once the scene investigator has considered the events prior to their arrival they must now consider what actions are then required. It is at this point that they assess whether they are the suitable candidate for examining the required areas. Direct contact with the suspect may prevent the attendance and examination of the scene itself. In relation to material that would be easily transferred such as fibers, paint, glass, or DNA-rich material, then it must be avoided.

Further thought is also necessary as although not previously involved in that particular enquiry the scene examiner may have previously examined an area in another scene that may contaminate their next examination. If a scene investigator is asked to examine a person suspected of firing a gun, then the recent handling by the investigator of a firearm in another case would make this latter examination totally inappropriate without taking vigorous steps to decontaminate first. It may be possible to pursue this examination safely with certain when appropriate safeguards in place as will be discussed later. There is however a risk that contamination may occur which will undermine the examination. So if there is a better candidate for conducting the examination available, then that should be pursued.

It may not always be possible to take into account at the time matters that only become relevant later. Although contamination may occur, the properties of a particular type of material and whether it can be transferred accidentally are particularly relevant. Directional blood staining is a clear

example of this as it cannot be transferred by wiping after the event as the shape of the deposited material has evidential value itself. So too, a mark or impression of an object without direct contact of the items. This is not so with trace DNA-rich material. Potential contamination of material may only occur in one direction. For example a scene investigator may take and seal the clothing of a person suspected of breaking a glass window. They then go to the scene where they also take control samples of the glass from the window frame. No contamination of the clothing by glass could have occurred. This is not the case if they go to the scene first and later personally obtain the suspect's clothing. The clear recording of the actions of the scene examiner at the time of the original and subsequent examinations is obviously important. This is also the case in protracted inquiries where proper control must be kept of all potential evidence.

Actions Within the Examination

The need to use disposable overshoes, overalls, and gloves at every opportunity is good practice. These items must be discarded after use in a way that cannot lead to contamination. The composition of personal protective clothing such as overalls must be suitable for the purpose (white paper, for example) and free from any contamination. Every effort must be made by the scene investigator not to contaminate one suspect with material from another similar scene. The example of potential contamination of firearm residues from another firearm is relevant here.

Contamination between unrelated scenes and suspects can be minimized by the use of separate cases or bags of equipment and consumables for the examination of scenes, vehicles, and suspects. So a case for crime scene examinations and a separate one for the examination of persons is a sound first step. There should under no circumstances be a movement of any material (even the most trivial such as labels of sealing tape) between the two. Carefully considered control samples (as will be described later) should be taken to demonstrate if any contamination has occurred. Where there is any doubt then control samples should be taken. Many forensic science laboratories or their suppliers provide kits with control safeguards included. This does not relinquish the responsibility of the examiner to consider the location, equipment, and personnel issues before sampling. A properly taken but positive control although unwanted in any enquiry is there to safeguard the suspect against matters outside the control of the scene examiner.

The Use of Blanks and Controls

Control samples are taken to determine if there is any background contamination. Properly taken they may include non-disposable equipment being used, samples of the environment of the examination (in the case of the examination of an individual) or the area around suspected material (without touching the suspect material itself). Blank samples may include a sample of the types of consumables used (an unused

bag from the same stock) again to monitor and demonstrate that they are free of any material which may be important in the examination. Blank samples include materials such as bags, containers, and tape. Blanks and then control samples should always be taken prior to the sampling of the suspect material as to do so after may contaminate the blank or control itself.

Blanks and controls are equally important to within scene contamination issues, that is, relating to movement within the same scene. If steps are not taken to change personal protective clothing and take blanks and controls within a single scene it may be possible to contaminate trace material from one area to another within the scene. The significance of this may only occur later when the statements of witnesses and the interview record of suspects show that a particular point needs to be proved or disproved. The consequence of this may be that it is not possible to determine if a witness, suspect, or scene examiner moved material within the scene. The change of personal protective clothing between zones (such as rooms within a scene) at natural breaks or when the examiner even momentarily leaves and reenters the scene cordon, limits the risk of contamination within the scene as a whole and as the examination progresses.

Many forensic science laboratories or their associated consumables suppliers prepare and monitor sampling kits for examinations such as DNA, firearm discharge residues, or metal traces. If the kit itself is not laboratory prepared and monitored, then blank materials should also be obtained before obtaining controls. When two suspects have already been detained at the same location and sampling is required from both, then the same trained operator can be used provided that consideration has been given to again discard disposable material such as gloves and the appropriate areas are cleaned and that the blank and control samples are obtained. This is certainly the case when obtaining hair combings from two persons suspected of previously wearing discarded woolen masks from a scene. Best practice suggests that two examiners should be used, one sampling each suspect. But what if there is only one individual available and the only additional person available is inexperienced or unwilling to take the sample? However well briefed that person is (by the scene examiner), this apparent option may be ruled out in favor of the trained examiner sampling both suspects while taking appropriate and disclosed safeguards. The established method of combing vigorously the subject's head hair with a seeded comb over a sheet of paper may not contaminate the gloved hands or forearms of the operator. But the words 'may not contaminate' are not good enough. There needs to be some proof that the safeguards have been successful and the procedure is sound. Before sampling each suspect, the scene examiner should wash their own hands and forearms only then obtain a blank tape and then a control taping of their own hands and forearms before sampling the suspect. Finally, if the suspect is wearing a woolly sweater it may be prudent to take this after the combing or obtain a sample of it in order to eliminate it from any material found in the head hair.

Thought must also be given to contamination from unrelated scene to scene, where the common denominator is the scene examiner or investigators. Although this may not be as important as that from scene to suspect, it is still

contamination. In general, where material is being obtained, then new packaging must be used and all disposable equipment such as overalls, overshoes, or even scalpel blades discarded. The mere wearing of disposable protective and clean clothing should not solely satisfy contamination considerations. What it will do is reduce at worst and prevent at best, a transfer of material between operator and scene and removal of material from the scene by the examiner. Where equipment is reused such as brushes, tools, and heavy duty protective safety clothing, then they must be thoroughly cleaned after use. The taking of control samples from them at the time of next use will determine if the cleaning process has been thorough and successful. Where material may become easily contaminated by accelerants such as a bag taken into an arson scene, but not used, then they should be discarded and destroyed so that they cannot be reused.

Case Example Bad Practice

A supply of nylon bags for the preservation of accelerants (from either petrol bombs or the clothing of suspects) is retained within the custody area of a police station.

On one occasion, an officer recovers a large petrol container and uses one of the bags to package the item, realizing that the bag is too small he chooses a larger bag and puts the first back into the stock cupboard.

A short time later an officer arrests a suspect for a different petrol bomb offense, bringing him to the custody area. On seizing the suspect's gloves, they place them in the contaminated bag obtained from the stock cupboard.

On examination of the gloves in a laboratory environment, the discovery of trace accelerant within the bag (particularly in the absence of a suitable control from the crime scene) may suggest contact with accelerants, which may not be the case.

The lessons from this are:

1. Packaging materials should never be reused.
2. The supply of packaging materials should only be handled and controlled by trained individuals who maintain their integrity.

The consequences of contamination are a real problem that must be fully considered particularly in field situations. Careful consideration must be given to the actions of others prior to the commencement of any crime scene examination. If an area has been contaminated, then the direction of the contamination may result that only a one-way transfer could have occurred. The examination for a transfer in the opposite direction or material that cannot be easily contaminated may still be appropriate and safe. The discovery and disclosure of this information is wholly professional.

Demonstrating the Integrity of Items and Investigations

Demonstrating that an item is free from contamination is as important as minimizing it.

The recording of accurate notes relating to the integrity of the scene and its examinations can support this by the:

- statement and oral accounts of witnesses
- actions of the first officers
- containment of the scene
- setting of a scene cordon
- maintenance of a log detailing who entered and left the scene and when
- continual taking of photographs of the scene as it is examined
- notes of any briefing given to those entering the scene
- scene examination/investigation plan
- record of sources and control of consumables
- details of search and examination
- details of protective clothing worn, by whom and when it was changed
- details of the retention and/or destruction of personal protective clothing
- details of the retention and/or destruction of consumables
- taking and retention of any blanks and controls
- list of all items recovered and retained
- steps taken to preserve, protect, and package items
- storage of recovered items
- movement of items
- details of any examinations made of recovered items
- final disposal of recovered items

Conclusion

The risk of contamination is specific to each evidence type and the circumstances of the scene and its examination. Separation from any outside source of the material under investigation and the ability to demonstrate that this has taken place are essential to maintain the integrity of the investigation and any interpretation or conclusions gained from it.

Forensic Intelligence Analysis

LR Rockwell, Forensic and Intelligence Services, LLC, Alexandria, VA, USA

© 2013 Elsevier Ltd. All rights reserved.

Glossary

Forensic intelligence analysis The process of analyzing forensic problems in the most accurate manner possible in order to create logical, unbiased analyses concerning probable past events.

Intelligence analysis The process of analyzing national

security and intelligence problems in the most accurate manner possible.

Mental models Simplified information-processing strategies that are inherent in the human brain.

Structured analytic techniques Logical, proven structures for critical thinking.

Intelligence Analysis and Forensic Science

Forensic scientists and national security intelligence analysts have similar occupations: on a daily basis, practitioners in both groups must answer questions that require them to know the unknowable. For intelligence analysts, knowing the unknowable helps them forecast future events that may impact national security. For forensic scientists, knowing the unknowable helps them better understand the past in order to help solve crimes. The information that forensic scientists and intelligence analysts need to perform their vital roles effectively is unknowable for many reasons. Crimes, like threats to national security, occur as part of complex social situations that are often difficult for scientists and analysts to discern. Necessary information is often unavailable, sometimes because it is kept secret by criminals or intelligence targets. Moreover, these practitioners' ability to apply logical, critical thinking to these questions is negatively affected by biases inherent in human thought processes. The intelligence community has developed analytic tools and techniques to help analysts answer national security questions more effectively in light of these difficulties; in essence, to help them better 'know the unknowable.' Forensic scientists can use these same critical thinking and reasoning tools to help them answer questions about crimes more effectively and accurately.

What Is Forensic Intelligence Analysis?

The proven processes used by intelligence analysts – whose work shares many similarities with forensic practitioners' – should be the basis for a definition forensic intelligence analysis, or forensic analysis. The analytic processes developed and used by the intelligence community can provide substantial benefits to forensic practitioners and will be examined first.

Intelligence analysis can be defined as the process of analyzing national security and intelligence problems in the most accurate manner possible. The result of this process is logical, unbiased intelligence concerning potential future events and probable past events. The process requires the appropriate use of structured analytic tools and techniques, which are used to analyze facts gathered through the traditional research process. The facts used in an analytic project should be drawn from as many data sources as is feasible and appropriate, given the

project's time and information constraints. This analysis is particularly valuable to intelligence consumers because it facilitates the production of judgments and assessments which are based on, but provided in addition to, the facts gathered during the research process. These judgments and assessments are typically the most important part of any intelligence product, and are often referred to as the 'value added' to the final product. Thus, the value of the analytic product far exceeds the facts on which it is based. Because of this, the intelligence analysis process is often described to those who are unfamiliar with the profession as 'adding two plus two and getting a total greater than four.'

Analysis produced using structured analytic techniques is significantly more likely to be accurate than analysis produced without the aid of such techniques; however, even intelligence produced by the analysis process described above cannot always accurately predict future events or recreate past events. Intelligence analysis has limitations; namely, it cannot accurately reveal future or past events in their entirety as would a fortune teller, medium, or wizard in a story. Instead, the intelligence that results from this process consists of predictions and judgments that vary in confidence (the perceived likelihood of accuracy) based on the quality and quantity of information available to the analyst at the time of analysis. Regardless of the confidence level of intelligence created using structured analytic techniques, this intelligence will almost always be more accurate than intelligence created without the benefit of the intelligence analysis process and its attendant tools, techniques, and practices.

Although forensic intelligence and forensic intelligence analysis are inseparable, forensic intelligence has received the bulk of the forensic community's attention. Forensic intelligence, which is the end result of the forensic intelligence analysis process, can be used on its own or reanalyzed in conjunction with other pieces of evidence to develop more new forensic intelligence. Examples of forensic intelligence include but are not limited to analytic opinions such as a fingerprint 'match,' the exclusion of a suspect based on DNA evidence, or the determination that a knife in evidence is consistent with the knife used to stab a specific crime victim. Forensic intelligence can be used to develop investigative leads, to show trends and patterns within and between crimes and jurisdictions, to help strategic decision makers determine the best possible use of resources or course of action for a

laboratory or police department, and to inform national security analyses. In part because each subsequent analysis has the potential to compound errors in the original forensic analysis, a greater focus on forensic intelligence analysis is necessary to ensure that initial and subsequent forensic intelligence products are as accurate as possible.

Establishing a process for conducting analysis in the forensic science discipline will improve the products that forensic scientists provide to citizens, investigators, prosecutors, and defense attorneys, such as reports or testimony. The process necessary to ensure that forensic analysis is logical and unbiased can be successfully borrowed from the analytic process already in use by the intelligence community. Using these existing techniques will not only help improve the quality of forensic intelligence analysis, but it will allow the forensic science discipline to avoid duplicating research, which has already been conducted in the fields of psychology and intelligence analysis, that is relevant to improving the quality of analysis. The tools necessary to improve the quality of forensic analysis are conspicuously absent from this relatively young discipline's toolkit, and could be easily added by borrowing the preformed concepts from the intelligence community. The structured analytic techniques used by the intelligence community should be among the most used of the forensic community's tools. With regular use, these tools could resolve many of the issues of analytic accuracy that have raised questions about the validity of the forensic science and the forensic community.

Forensic intelligence analysis, therefore, can be defined as the process of analyzing forensic problems in the most accurate manner possible in order to create logical, unbiased analyses concerning probable past events. The process requires the appropriate use of structured analytic tools and techniques, in conjunction with the use of multiple data sources whenever feasible and appropriate. Forensic intelligence analysis also provides 'value added' to its customers by taking raw facts, such as a shell casing, blood, or a fingerprint, analyzing those facts and providing the resultant judgments and assessments to forensic customers. Investigators, prosecutors, and defense attorneys would have little use for forensic evidence if all they received was the evidence itself.

Similarities between Forensic Science and Intelligence Analysis

The tools and methods used by intelligence analysts can be applied to forensic science because the work of intelligence analysts and forensic practitioners is very similar. As was mentioned earlier, practitioners in both groups must know the unknowable. This task is understandably difficult, whether performed by an intelligence analyst who typically needs to understand how future events may unfold, or by a forensic scientist who needs to understand how past events may have unfolded. Intelligence analysts typically answer questions which may impact national security, such as 'Will a terrorist attack occur in Washington DC in the next 6 months?' 'Will dictator X declare war on country Y within the next 2 weeks?' or 'Will the outbreak of flu in country Z spread to the United States?' Forensic practitioners, on the other hand, typically ask

crime-related questions that focus on past events, such as 'Is the DNA found on victim A consistent with the DNA of suspect B?' 'Could the fibers found at the crime scene have come from the shirt owned by suspect C?' or 'Could this knife be the knife that was used to stab victim D?'

When answering questions like these, both intelligence analysts and forensic practitioners must provide sound analysis to their customers. To do this successfully, practitioners in both groups must do the following:

- Make sound, unbiased judgments about probable past or future events.
- Employ logical argumentation.
- Provide objective judgments and insights.
- Use critical thinking skills and structured analytic techniques. This helps prevent bias and ensure logical reasoning, thereby increasing the odds that judgments will be objective, logical, and unbiased.
- Uncover trends and show explicit connections between related events, persons, places, etc.
- Interpret information, rather than simply describing information.
- Incorporate alternative analysis (additional explanations of how events may unfold or may have unfolded) when appropriate.
- Exhibit consistency of analysis over time, or highlight the changes in the analysis and explain the reasons (new information became available, etc.) for those changes.
- Evaluate the quality and reliability of information that may be used in analysis in order to ensure that each piece of information receives appropriate consideration in the analysis. High-quality information from highly reliable sources should have more weight in the analytic process than low-quality information or information from unreliable sources.
- Distinguish between underlying facts and the practitioner's assumptions and judgments. This must be done so that the customer can clearly and easily distinguish between what is true and what might be true, in order to prevent future analytic errors caused by analysis predicated on analytic assumptions – which may later prove to be false – instead of facts.
- Provide the best analysis possible.

Both groups must perform these tasks while limited by unfavorable conditions. Specifically, both intelligence analysts and forensic practitioners will frequently find that they have neither enough time nor enough information to perform these tasks as well or as completely as they would like to. Forensic practitioners and intelligence analysts must both:

- *Deal with limited or incomplete information.* Crime scenes rarely contain all of the information necessary to solve a crime. Intelligence analysts researching specific issues know that most situations are too complex to understand in their entirety. This is complicated by the fact that, in almost all situations, 100% of the information pertaining to that topic simply is not available. Analysts who work on topics related to potential future events know that unanticipated developments can skew analysis.
- *Deal with unreliable, conflicting, or ambiguous information.*

- *Deal with denial and deception.* Suspects, witnesses, and intelligence targets may intentionally or unintentionally withhold important information or lie in order to mislead investigators and analysts.
- *Deal with information in the context of volatile and unknowable social situations.* Analysts cannot always be aware of the cultural and social forces acting on intelligence targets, victims, witnesses, or criminals. Without awareness of these factors, it can be difficult for practitioners to understand the motivations of these actors, which can skew analysis.
- *Work within limited time frames.* The time available to process a crime scene or research an issue is limited. Some types of evidence degrade over time. Other types of evidence, such as the temperature of an object, are time sensitive.
- *Collect appropriate information.* Both analysts and forensic practitioners can collect too much information, thereby gathering irrelevant information that makes it more difficult to conduct analysis. Analysts researching an issue may find that their searches have gotten off topic, or find that they are collecting deceptive information supplied by the intelligence target.
- *Identify information gaps.* Identifying what is not known is vital to both groups, in order that they can do their best to find the missing information to do analysis with the most complete picture. Crime scenes rarely contain all of the information necessary to solve a crime. Gaps, once identified, must be filled through other means, such as interviews and traditional investigation.

Intelligence Failures

When intelligence analysts fail to meet the criteria described in the previous section, and thus to properly forecast future events, the result is what the intelligence community calls an 'intelligence failure.' Some of the most infamous intelligence failures include the intelligence community's failure to predict the 1941 attack on Pearl Harbor; the 1973 Yom Kippur War; the 1990 invasion of Kuwait; the 1998 Indian nuclear tests; the 2001 Al Qaeda attacks in New York City, Virginia, and Pennsylvania; and the 2003 declaration that Iraq was in possession of weapons of mass destruction.

The forensic science discipline has had its own intelligence failures, which will be called 'forensic failures' for the purpose of this article. Several of these have been well publicized by the media, such as the 2002 Washington DC sniper case, in which forensic profiling techniques predicted that the sniper was a middle-aged white male with military training who was acting alone and driving a white van. The sniper was actually two black men acting in concert and driving a blue Chevrolet Caprice; only one of the men was middle aged and had been trained in the military, the other was a teenager. The Madrid train bombing case, in which the Federal Bureau of Investigation (FBI) aggressively pursued false leads, is another example of a forensic failure. In this case, the FBI matched a fingerprint found on a bag containing detonating devices to a US citizen, Mr. Brandon Mayfield, who was subsequently arrested. The FBI, which claimed that the fingerprint was '100% verified' as belonging to Mr. Mayfield, refused to concede that the

fingerprint may not have belonged to Mr. Mayfield long after Spanish police presented compelling evidence that the fingerprint had actually been left by an Algerian national with a criminal record and a Spanish residency permit. Research also has shown that forensic failures occur in fingerprint analysis: when told that investigators believe that the suspect is 'definitely' guilty, that the suspect committed a violent crime, or that the print and suspect were previously matched, fingerprint examiners are much more likely to declare matches where there are none.

The roots of intelligence failures and forensic failures can almost always be traced to simplified – and often faulty – information processing strategies that are inherent in the human brain. These simplified information processing strategies cause errors in thinking, known as cognitive biases, which are compounded by other factors commonly at work in forensic and intelligence analyses, such as lack of information, the presence of disinformation, lack of time to conduct additional analysis or further research, and so forth. These biases are purely functions of human information processing strategies, and are not motivated by emotional or intellectual predispositions toward certain judgments.

These simplified information processing strategies are known as mental models. The thought processes that result from mental models are consistent, predictable, subconscious, and – in spite of the previous paragraph's evidence to the contrary – extremely helpful to the species. Mental models are part of the evolutionary process, and allow humans to process otherwise incomprehensible volumes of information. By helping humans deal more effectively with ambiguity and complexity, these mental models have also helped the species to survive and thrive.

The cognitive biases that result from these mental models are also detrimental: they commonly cause humans to jump to conclusions, miss the obvious, and simply draw inaccurate conclusions. Cognitive biases interfere with logical thinking in a number of ways. First, these biases cause people to perceive what they expect to perceive, which often occurs even if evidence initially exists that should discredit the person's perception. Adding to this, these mindsets, whether based on accurately or inaccurately perceived information, form very quickly but tend to resist change for a prolonged period of time. When new information becomes available, it is most often assimilated into the existing mindset. If the new information conflicts with or refutes this mindset, it is frequently dismissed as unreliable or simply ignored. Simply, humans' initial mindsets – which, in this case, would be well thought of as hypotheses – will frequently interfere with accurate analysis even after better, more complete information becomes available.

The forensic failure associated with the FBI's handling of the Madrid train bombing case is an excellent example of how mental models can interfere with logical thinking and, therefore, with good forensic science. Prior to the train bombing, the FBI had identified Mr. Mayfield, who converted to Islam after marrying an Egyptian woman, as a potential Islamic extremist. Based on the volume of surveillance dedicated to Mr. Mayfield and his family, it is likely that agents had become convinced that Mr. Mayfield was, in fact, a terrorist. When Mr. Mayfield's fingerprint came back as one of 20 others that

was a possible match for the print found on the bag containing the detonators, this information – which should have been viewed with caution – was instead used to proclaim that the print had been ‘100% verified’ as belonging to Mr. Mayfield, and was thus assimilated into the agents’ existing mindset. When the Spanish police examined the prints and found them to be inconsistent with Mr. Mayfield’s prints, this evidence was ignored. It was not until the Spanish police matched the prints to the Algerian criminal and a warrant was issued for his arrest that the FBI recognized and conceded its mistake. The US District Court judge who presided over a subsequent lawsuit found that the FBI had ‘fabricated and concocted’ evidence against Mr. Mayfield, which is consistent with the FBI assimilating new evidence into its existing mindset, and dismissing evidence which did not fit that mindset.

Cognitive biases are extremely difficult to overcome. Even when one is aware of them, it is rarely possible to stop or diminish their effects, as the mental models that cause them are ‘hard-wired’ into human brains. It is likely that the FBI analysts who worked the Madrid train bombing case had at least heard of them, and it is all but certain that the Central Intelligence Agency (CIA) analysts who contributed to the Iraqi weapons of mass destruction intelligence failure had learned about cognitive biases as well as techniques used to overcome their effects during basic analytic training at CIA.

The Benefits of Structured Analytic Techniques

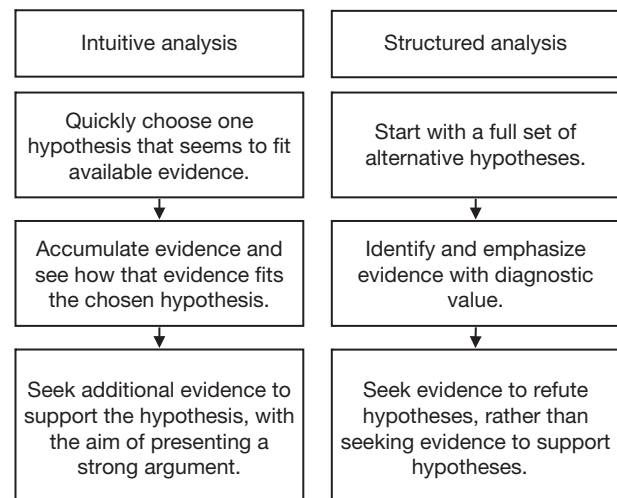

Structured analytic techniques, which are logical, proven structures for critical thinking, can help intelligence analysts and forensic practitioners overcome the effects of cognitive biases and deal more effectively with bad, limited, or false information. There are many structured analytic techniques, each of which can be used at a different stage of an analytic problem to ensure the logic of the analysis. Although not every technique is appropriate for every analytic problem, every analytic problem will benefit from the use of appropriate structured analytic techniques. Structured analytic techniques are commonly used in business to ensure that corporations and other organizations make the best possible decisions.

Structured analytic techniques help critical thinkers overcome cognitive biases in many ways. These techniques help allow the imposition of analytic will and logic on the subconscious mind, thus overcoming the effects of flawed mental models. They also help thinkers focus their analysis, and increase the accuracy and efficiency of human thought processes. In the process, they help the mind make sense of complex problems, allow the mind to focus on only one element of the problem at a time, and compare those elements against each other. This is far different from trying to solve a complex problem ‘in one’s head,’ which often makes it difficult to clearly see the scope of the problem, let alone identify, isolate, and compare each element of the issue. Structured analytic techniques also facilitate visual analysis, which harnesses more effective brainpower in addition to doing all of the above.

Structured analysis is very different from the intuitive analysis that is commonly used by persons writing college-level papers and reasoning their way through everyday events. It is common for persons who use intuitive analysis to arrive at

incorrect conclusions. This process is driven by the mental models described in the previous section. Intuitive analysis starts when the individual identifies one potential hypothesis or explanation for events. Because of the effects of mental models, it then becomes very difficult for that individual to consider alternative hypotheses or explanations. The chosen hypothesis typically appears to mesh with the evidence the individual has observed to that point, even if the individual has done very little research about and has very little understanding of the issue at hand. When the individual accumulates new evidence and compares it to the hypothesis to see if the evidence fits, or supports, the chosen hypothesis, mental models come into play again and evidence that does not support the hypothesis may be dismissed or ignored. Additional supporting evidence will be identified and used to create a strong argument for the chosen hypothesis, even if evidence which should have discredited the hypothesis has been discovered.

Structured analysis is much more likely to produce accurate conclusions than intuitive analysis. This broad process is supplemented along the way by a variety of structured analytic techniques designed to ensure the step-by-step integrity of the process. Unlike intuitive analysis, this process begins with the identification of the widest possible array of explanations, often called a ‘full set of alternative hypotheses,’ for the observed activity. At this stage, structured analytic techniques will be used to help identify this range of hypotheses and identify underlying (and possibly incorrect) assumptions. Next, research will begin, and the analyst will identify evidence with diagnostic value. Structured analytic techniques designed to determine the quality and reliability of evidence will be used at this stage. The collected and analyzed evidence will then be compared to the available hypotheses, and used to discredit, rather than support, the hypotheses. The structured analytic techniques used in this process prevent analysts from falling prey to the effects of mental models that occur in the intuitive analysis process.

The use of structured analytic techniques can have enormous benefits for forensic practitioners. Not only do these techniques help practitioners overcome cognitive biases, they also clarify practitioners’ thought processes and help them identify fallacies, information gaps, and errors in logic. These techniques also help

practitioners deal more effectively with limited time and resources, and limited or ambiguous information. The use of structured analytic techniques also improves group work, increases consistency among practitioners, provides records of the analytic process, and makes it possible for one practitioner to pick up the analytic process where another left off. By forcing practitioners to order their thoughts logically, the use of structured analytic techniques also helps them to communicate more effectively and express facts clearly. Altogether, use of these techniques improves the accuracy of the practitioners' analysis and communication, making the final product more useful for investigators, prosecutors, and defense attorneys who rely on forensic practitioners' services.

Fingerprints

Introduction

Fingerprint identification is one of the oldest forensic tools used by police forces to investigate crime. The concept of identifying individuals using their fingerprints began in Asia, and the spread of the British Empire allowed observation and development of the process by civil servants in India who then publicized the practice in the United Kingdom. Initially, fingerprints were used to sign documents, but their use was expanded and developed before being adopted by the police in England at the turn of the twentieth century both as a means to identify repeat offenders and also to link individuals to crimes. It became accepted as one of the best forms of evidence available, a definitive way to identify an individual or to connect them to a crime scene. When DNA evidence was first introduced, it was called 'DNA fingerprinting' in an attempt to link it to the perceived strength of fingerprint identification. The field has enjoyed almost a century of high regard but, in recent times, a small number of highly publicized errors coupled with developments in other forensic sciences have meant that it is no longer universally viewed as the 'gold standard' of evidence.

What Is a Fingerprint?

A fingerprint is an impression left behind by the skin found on the inner surface of the fingers. The skin on this area is called friction ridge skin, and is found on the palms of the hands, as well as the toes and soles of the feet. Its main evolutionary use is for gripping, which is why it is only found in these areas; the same type of skin is found on the hands and feet of primates. Friction ridge skin comprises many tiny ridges and furrows, covering the surface. The ridges do not flow continuously but bend and curve, stop and start, come together and split apart, creating patterns and unique arrangements of features. The ridges form before birth, as the fetus develops in the womb, and barring a deep-seated injury which penetrates through the epidermal layer of skin, their arrangement will remain unchanged until after death. Their configuration is a combination of many factors including the stresses and strains on the skin in the womb as it develops, hormones, and genetics.

Each ridge contains many sweat pores, which run along the crest of the ridge. These are always exuding sweat, and when a receptive surface is touched this sweat is left behind, leaving an impression of the ridge pattern. An impression in sweat will be left on every surface touched, but the impression is only of use if the surface is smooth and receptive. Flat plastic and glass are excellent surfaces to recover fingerprints from; rough surfaces like wood are more difficult. Recovering a print from a rough, textured, powdery surface like stone is unachievable. A mark left in sweat can be almost invisible; hence the name latent print, derived from the Latin 'latere' meaning hidden. Fingerprints

can also be left after touching contaminants such as paint, oil, or blood, and in malleable substances such as putty.

Fingerprint examiners study the features of friction ridge skin, which can be divided into three areas or levels: level 1 is the pattern type and ridge flow, level 2 is the ridge characteristics, and level 3 is pores and ridge edge shapes. Each of these levels represents a more minute level of detail; the following sections will describe each of these in more detail.

Pattern Type and Ridge Flow

The topographical surface of the hand will determine the general pattern formed by the ridges. As they develop, they take the path of least resistance, and so will flow over flat areas, and around raised areas. The three main patterns types are known as arches, loops, and whorls, shown in [Figure 1](#), but there are many variations and combinations within these pattern types.

Looking at the patterns, it is possible to imagine the arch pattern being formed by ridges flowing over a flat area of skin; the whorl pattern resulting from ridges flowing round a raised area of skin; and a loop pattern being the result of a raised area on the right or left side which the ridge flow curves away from.

Ridge Characteristics

The ridges themselves do not flow in unbroken lines across the skin. They can come to a stop, making a feature called a ridge ending, or they can split apart, making a feature called a bifurcation. These features are known as ridge characteristics. These two basic characteristics can combine to form others, as shown in [Figure 2](#).

It is the appearance and relative position of ridge characteristics that comprise the main area of comparison for fingerprint examiners.

Pores and Ridge Edge Shapes

On many prints, the ridges may appear to the naked eye to be solid lines, but on magnification, the pores which run along the crest of each ridge may be visible. They will appear as white dots inside the black of the ridge. The pores themselves are not evenly spaced or of uniform size, and so their size and location can also be used as a comparison feature.

The ridges are undulating and bumpy in places. On a fingerprint of good quality, the shape of the ridge edges can also be used as part of the comparison process. [Figure 3](#) shows a magnified section of a fingerprint, showing the pores and ridge edge shapes.

The appearance of pores and ridge edge shapes is affected by several factors: the quality of the print, pressure used, the smoothness of the surface the print has been left on, and the type of ridges an individual has. Some individuals will have thick ridges, making pores and edge shapes more apparent,

Figure 1 Three main pattern types.

Figure 2 Ridge features.

while others will have fine ridges making these features less apparent.

Other Discriminating Features

All of the features described above are biological features which develop before birth and are permanent. There are other features of the skin on the hands and feet which can be used for identification purposes. The friction ridge skin on the hands and feet is marked by creases, some permanent, where the joints bend, for example, and others which may change and develop over time, depending on how the skin is used, and as the skin ages.

If the skin is damaged badly enough to penetrate through to the dermal layer of the skin and affect the layer which holds the 'blue print' for the ridge pattern, the layout of the ridges will be affected. This will result in the formation of a scar. Although this will alter the fingerprint, the scar becomes an identifying feature itself as once the scar pattern is set, it will become part of the regenerating pattern of the ridges. **Figure 4** shows a fingerprint with a large permanent scar.

Marks and Prints

In fingerprint identification, two terms are often used to distinguish between the two different types of fingerprint which are analyzed. Fingerprint identification consists of a comparison between an unknown fingerprint recovered at a crime scene and a known fingerprint from a fingerprint form. The fingerprint from a crime scene is commonly known as a 'mark,' and can vary greatly in quality. It may be a very high-quality reproduction of the skin's surface, showing a high level of detail including ridge flow, pattern, ridge characteristics, and even pore and ridge edge shape detail, or it may be of very poor

Figure 3 Enlargement of fingerprint showing pores and ridge edge shapes. Reproduced from Duncan JH (1942) *An Introduction to Fingerprints*. London: Butterworth and Co.

Figure 4 Fingerprint showing permanent scar.

quality, with details obscured by dirt, the texture of the surface, movement, pressure, smudging, or overlapping fingerprints.

In contrast, the fingerprint from a fingerprint form, known as a 'print,' is almost always of good quality in comparison to the unknown mark. These fingerprints are taken in controlled circumstances, usually by a police officer. These prints can be taken by two different means; by coating the finger in ink and rolling it smoothly across paper, or using an electronic device known in the UK as Live Scan, which uses a computer scanning device to scan the surface of the skin and then prints this onto paper. Although these are usually of very good quality, this is not guaranteed; prints can still be of poor quality due to dirt or sweat on the hands, too much pressure, or if the finger is moved while being printed.

Recovery of Fingerprints from Scenes

Crime scene examiners will examine every scene to attempt to recover fingerprints. Some marks may be visible to the naked eye; others may need some form of development.

Generally, marks left in sweat are invisible, and will need to be developed in order to be recovered. The most common method used is dusting powder. The crime scene examiner will lightly brush a fine powder over an object or surface area, and the powder will adhere to any fingerprints left there. Any marks are then recovered by a process known as 'lifting'; a piece of adhesive tape is smoothed over the mark and then carefully peeled away and adhered to a clear acetate sheet. The powder is transferred to the tape, and the mark is then visible on the acetate.

This method is generally used for smooth, clean surfaces. There are a range of powders available, the most commonly used being aluminum and magnetic metal flake powders; granular powders are also available in a variety of colors. The type of powder and the color used are dependent on the surface being examined; granular powders are often photographed rather than lifted, and colors can help contrast with the color of the underlying surface.

Chemical Development

Articles are often removed from a crime scene to be treated at a lab. There is a wide range of treatments available to develop fingerprints on different surfaces; many of these require chemical processes not possible at the crime scene. Liquid chemical treatments such as ninhydrin and 1,8-diazafluoren-9-one (DFO) are used to develop prints on porous surfaces such as paper and are probably the most common chemical treatments. Cyanoacrylate (super glue) vapor can develop prints on smooth nonporous surfaces, and vacuum-metal deposition employs vacuum-coating technology, which uses thermal evaporation of gold and zinc to coat surfaces such as plastic bags and reveal fingerprints on the surface. Different chemical treatments will react with different constituent components of sweat and some can be used in sequence to get the best possible results.

Fingerprint Practice

Fingerprint Comparison Methodology

Once fingerprints have been recovered, either by the crime scene examiner or at the lab, they will be sent to the fingerprint department to be worked on. A fingerprint examiner will use a methodology known as analysis, comparison, evaluation, and verification (ACE-V) to conduct their analysis of a fingerprint. In most cases, when fingerprints arrive at a fingerprint department, they will be accompanied by a list of individuals to be compared against the crime scene prints. These individuals may be quoted as suspects: people suspected of committing the crime, or as eliminations: people with legitimate access to the scene or property and whose prints might therefore be expected to be found. ACE-V describes the various stages of the comparison process.

During the first stage, analysis, the unknown mark is studied. Details such as the surface the mark has been left on, the substance it has been left in, and the development medium used will be noted where possible. The mark itself will be analyzed to determine the quantity and quality of information contained within it, such as pattern type, ridge flow, presence of scars, creases, ridge features, and pores. Using all of this information, the examiner will use his/her judgment to best determine which area of skin, finger, or palm, left the mark.

If there is too low a level of information contained within the mark, the examiner will deem it insufficient; there is not enough information present to make an identification.

The second stage is comparison; the unknown mark is compared against a known print. The examiner is looking for features in sequence and agreement, with none in disagreement, unless there is an explanation for such disagreement.

Once the mark and print have been compared, the next stage is evaluation. All of the information found is weighed up

in the examiner's mind, and a conclusion is reached. Current practice, based on professional culture, allows for three different conclusions:

1. Identified: the mark was left by that individual.
2. Not identified: the mark was not left by that individual.
3. Insufficient: there is not enough information to reach one of the above conclusions.

Some jurisdictions allow for a fourth finding: inconclusive. This is used in situations where features are found in agreement, but there is not enough information to identify.

The final stage of the process is verification. Practices vary in different jurisdictions, but all identifications are verified by at least one other fingerprint examiner, working independently, before the result is passed out to the police. The verifier will carry out his/her own analysis, comparison, and evaluation of the mark and determine whether the mark is identified. An identification is only passed out as a result by the fingerprint department if it is agreed by all examiners who have examined it.

Figure 5 demonstrates the comparison process. The points highlighted can be seen on the mark, and found in the same location on the print. For example, points 1 and 2 form a lake, and are seen on the mark and the print. Looking at the mark, we can follow the ridge down and move one ridge to the right and find point 3, a bifurcation. Counting 5 ridges to the left from point 3, we find another bifurcation, point 4. Again, these points are found on the print. It is possible to work through all the points in this manner, finding them all in both mark and print, in the same relationship to each other.

Numeric Standards

Until recently, it was common for jurisdictions to work to a numeric standard in order to determine whether a mark was identified. In the United Kingdom, this standard was 16 points in common and in the United States of America, it was 12 points, although the Federal Bureau of Investigation (FBI) worked with a standard of 8 points.

In 1973, the International Association for Identification (IAI) declared that "no valid basis exists at this time for requiring that a predetermined minimum number of friction ridge characteristics must be present in two impressions in order to establish positive identification." The decision to require a minimum number of points in agreement for an identification arose as a way of ensuring commonality within a country between regions and police forces. The numbers decided

Figure 5 Mark and print showing eight corresponding ridge features.

upon were not the result of scientific research but rather on a need for safety and perceived objectivity.

The IAI announcement in 1973 prompted a move away from numeric standards, and many countries have now adopted a nonnumeric system. This development did create a problem; up until this point, an identification was easily explained by confirming that the required number of points had been found. Now something else was needed to replace it. A new explanation of fingerprint identification was developed by David Ashbaugh, a Canadian fingerprint examiner, and given the name 'ridgeology.' Ashbaugh concentrated on the way the skin is formed, and its uniqueness, to explain that scientifically there could never be an arbitrary quantity of points required; instead, it depended on the mark itself and the quality, quantity, and clarity of available information. He coined the term ACE-V as a way to describe the identification procedure, taking into account all available information and the unique formation of the skin to reach a conclusion.

Although many countries have been using a nonnumeric system for many years (e.g., the United Kingdom, the United States, Canada, Australia, and Norway), there are still countries that prefer to work to a numeric standard. Some examples of these would be Holland, Greece, Finland, and Spain, who use a 12 point standard, as well as Germany and Sweden, who use an 8–12 point standard.

Computer Technology

If after the comparison process has been carried out the mark has not been identified, or if there are no individuals quoted to be compared, marks can be searched against a computer database. In the United Kingdom, this database is called Ident 1, and in the United States, it is the Automated Fingerprint Identification System. In 2011, the UK fingerprint database contained prints for 8.45 million individuals. When a set of fingerprints is taken for an individual, it is loaded onto the fingerprint database. Fingerprint examiners can then scan a mark from a crime scene, encode it with visible features, and search it against the database. These searches can be local, regional, or national searches, and provide an excellent investigative tool, frequently providing 'cold' hits against unsuspected individuals. A computer search is however by no means perfect; it does not provide unverified matches and all results must be checked by a fingerprint examiner to be confirmed.

The latest development in computer technology is direct transfer of marks from recovery at the locus to the fingerprint department. At present, marks from a crime scene are generally printed and sent in hard copy or lift form to the fingerprint department, and this can result in a long processing time. Some areas of the United Kingdom are now beginning to use a form of electronic transfer, where fingerprints recovered from a scene can be photographed or scanned by a computer and sent directly to the fingerprint department, meaning that a delivery which might have taken days can now be conducted in seconds.

The Role of the Tenprint

Much of the public awareness about the uses of fingerprints relates to the recovery of fingerprints at crime scenes and their

comparison to prints from a suspect. Within criminal justice, fingerprints play another important role. On arrest, an individual's fingerprints are taken and immediately searched on a computer against all held fingerprint forms. By this method, it can be established whether the individual already has a criminal record, and can also confirm identity if a record is held. This ensures databases such as the Scottish Criminal History System and the Police National Computer in the United Kingdom remain accurate.

Current Issues in the Field

Recent developments in fingerprint practice and forensic science as a whole have opened up fingerprint identification to new discussion, debate, and criticism in the past decade. The profession developed in the Victorian era, when the public were very open and accepting of new scientific advancements, and little has changed in the way the profession conducts its work since those early days. Critics have argued that there are weaknesses in the foundation of fingerprint identification as well as concerns regarding the methods used to reach conclusions. Many of these issues have arisen due to a greater awareness of scientific practice within the legal system.

Daubert hearings in courts in the United States, regarding admissibility of evidence, have resulted in a desire within the fingerprint profession for scientific credibility, and this appears to have grown in strength since the removal of a numeric standard. Without a seemingly objective numeric standard, the concept of 'science' has been used to convey the authority and objectivity of fingerprint practice. This has led to heated debate; critics have been quick to argue that it is not a science, and, as a result, the implication has been made that if it is not science, then it is useless. The fingerprint professionals have denied this and say that it is a science, and therefore valuable. These arguments revolve around a misconception; value and utility are not restricted to science.

Uniqueness

The uniqueness of friction ridge skin is seen as one of the key premises of fingerprint practice. However, an identification is made on an examination of a mark left behind, which can be of widely varying quality, rather than the skin on the finger itself. The biological uniqueness applies to the finger, not the print left behind, and by asserting that a print is as unique as the skin which made it, the profession has ignored investigation into how similar two prints from different people can be. Most examiners will have seen areas of similarity between fingerprints from different people, but this has not been empirically studied. Although biological uniqueness is important, it is the ability to perceive this information which is crucial.

Infallibility and Certainty

Fingerprinting is synonymous with absolute certainty and absolute identification. This type of reporting arose in the early days of fingerprint identification, and early texts show that fingerprint examiners were not seen to be giving an opinion, but reporting a fact. It is unusual that, although fingerprint

identification is viewed as expert opinion evidence, the notion of conclusions as fact has not shifted. This view can still be found in recent publications, stating that the conclusions of fingerprint experts are absolute and final. Irrespective of whether or not this is 'scientific,' it is irrational to make claims of absolute certainty and therefore eliminate all other possible donors in the world. No matter how much experience an examiner may have, they will only have viewed a tiny percentage of the fingerprints in the world, and of those which they have examined, they will not be able to retain in memory all of the other prints they may have examined.

The McKie case in Scotland, the subject of the Scottish Fingerprint Inquiry, is an example of the inherent problems of attempting to be certain about a conclusion which can only be an inference. This case was the first time disagreements between experts was brought to the attention of the general public, and demonstrated that not all fingerprint examiners agree all of the time. The report, published in December 2011, concluded that fingerprint examiners cannot report their findings with 100% certainty, and that it should be recognized as opinion evidence rather than fact. This will have far-reaching effects on the profession.

Probabilistic Evaluation

One possible solution would be for fingerprint practice to adopt a probabilistic model for reporting their findings, rather than a categorical one. Although statistics were discussed by some of the founding fathers of fingerprints, it has until recently been rejected outright by the fingerprint profession. There are three common reasons given for the rejection of a probabilistic approach: the first is that friction ridge skin is unique. Suggesting the possibility of commonality between different prints would suggest the possibility of duplication, which is not deemed possible. The second is that there is currently no model which could be used to calculate a probability. This, however, is changing; at the present time, there are models under development and these will only continue to be refined and become more accurate. The final reason given is that a probabilistic approach would weaken fingerprint evidence. The fingerprint profession views the certainty of its conclusions as its main strength, but as questions accumulate about the logic of such conclusions, this is no longer the case.

Currently, it is difficult to determine the reliability of the conclusions of a fingerprint examiner as they are based purely on observations made by the examiner, using their personal experience, training, and ability. A probabilistic model may be a way to add a more objective verification of an examiner's opinion.

Error Rate

It has been stated that the error rate of fingerprint examination is zero. As errors within the field have been discovered, this has been altered to claim that the methodological error rate is zero; that is, any error is not with the methodology, but with the examiner. These arguments were made most widely by fingerprint examiners in the United States, attempting to defend fingerprint identification against criticism in Daubert hearings, when they were asked about the error rate of their field. More

recently, it has become widely accepted that such statements are not valid; the examiner is a key component of the process of fingerprint identification and it is illogical to discount their input.

Bias

Confirmation bias can be defined as "the tendency to confirm an initial theory or preconception and avoid disconfirming information" and is an unconscious aspect of how our minds function.

The concept of confirmation bias in the comparison process of fingerprint identification can take various forms:

- Being unconsciously affected by extraneous information, such as police case information
- Being affected by the known conclusions of others about the mark in question
- Rationalizing (explaining away) discrepancies because of a subjective confidence in the identification
- Being led by the known print to find features in the unknown, and poorer quality, mark
- Being more likely to observe features in agreement, and not notice areas of disagreement

Fingerprint examiners are trained to look for discrepancies as well as similarities, but the human brain is programmed to weight positive instances more heavily than negative ones, so it can be quite possible to dismiss negative factors. A small amount of research has been done in this area; some studies have suggested that bias has a strong effect on fingerprint conclusions, while others have suggested the opposite.

Conclusion

From the issues mentioned above, it is clear that fingerprint practice is at the beginning of a new era, with many issues to be resolved over the coming years. Currently, the main collection of knowledge used by fingerprint examiners is accumulated through their own experience, and 'common sense' explanations, passed down from one examiner to another. The future of fingerprint identification will likely see this knowledge supplemented by empirical research. Fingerprint analysis must be seen to be logical and its processes transparent; its findings able to be demonstrated. It provides a highly valuable tool to police forces, giving fast and economical results. The current debates do not discredit fingerprint evidence, but they highlight areas for improvement to ensure the field maintains its position as a significant part of forensic science.

Major Incident Scene Management

J Horswell, Australian Federal Police, Canberra, Australia

© 2013 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, volume 1, pp. 428–432, © 2000, Elsevier Ltd., with an updated Further Reading section supplied by the Editor.

Background

There are three critical operational stages of a criminal investigation. These are:

- control and coordination of the criminal investigation;
- the criminal investigation;
- the forensic investigation.

Normally the coordination of a major criminal investigation is delegated to a senior investigating officer; likewise a complex forensic investigation must be coordinated by a senior forensic investigator. To manage major incident scenes and multisited crime scenes the crime scene coordinator/manager must understand forensic science and criminal investigation. The crime scene manager must surround him- or herself with competent, skilled and qualified forensic investigators, not prima donnas.

This article only deals with the management of major incident scenes from a forensic investigator's point of view.

Scene Control and Coordination

Without proper control and coordination, information may not reach the crime scene investigator. This may lead to his or her efforts being aimless, and the leads uncovered may never be passed on to investigators for follow-up action. This is most important when the crime scene is large and there are several crime scene investigators present processing the scene, or where there are secondary scenes away from the primary scene. There must be a flow of information back and forth between the senior investigator and crime scene investigator. This is one of the functions of the crime scene manager.

Approach to Crime Scene Investigation

The examination of a crime scene and subsequent collection of potential physical evidence requires special skills, knowledge, and aptitude. The manner in which a crime scene examination is conducted may be a critical factor in determining the success of an investigation. The proper examination of a crime scene requires a disciplined approach and systematic application of the various observation, recording and collection techniques, as well as an in depth knowledge of forensic science.

Examining a crime scene is often a demanding task, and in many instances requires physical and mental stamina as well as team leader/member skills.

Forensic science has become a powerful aid to criminal investigations, with courts placing much emphasis on the results. Accordingly, the manner in which evidence is collected, the observations made and the results of tests and comparisons conducted, are vigorously examined by the courts.

A systematic approach to crime scene investigation will ensure:

- good coordination between investigation and crime scene examination teams;
- an efficient, effective, and thorough examination;
- less fatigue;
- orderly recording and collection of potential evidence;
- effective observations and deductions.

Initial Assessment

Before attending the crime scene it is important to obtain the best possible assessment of the circumstances relating to the crime. It is also important to receive a briefing from the senior investigating officer who has been appointed to conduct the investigation. From a forensic viewpoint, a crime scene coordinator should be appointed. This person will remain the focal point of contact between all the players who will subsequently become involved in the forensic investigation. This person should be a senior crime scene investigator who will be responsible for chairing all subsequent meetings with investigating police and for the coordination of all aspects of the forensic investigation. This includes the allocation of human resources to multiple scenes.

Homicide will be discussed here as the model crime scene as this is the most serious crime against the person.

Forensic investigators are in the same position as investigating officers. They need answers to the same questions: Who? What? When? How? Where? Why? Some of these questions can be answered at the homicide scene.

Who?

- Who is the deceased?
- Who reported finding the deceased?
- Who saw or heard anything?

What?

- What happened?
- What crime, if any, has been committed?
- What were the actions of the deceased?
- What were the actions of others involved?
- What are the witnesses saying?
- What injuries, marks, clothing, and personal property are on the deceased?
- What is the estimated time of death?
- What possible weapons were used?
- What cause of death information can be gleaned from the deceased?
- What was the manner of death?

When?

- When was the deceased discovered?
- When was the deceased last seen alive?
- When were the police notified?

How?

- How did the deceased get to the death scene?
- How long has passed between injury and death?
- How did the deceased sustain the injuries?

Where?

- Where was the body discovered?
- Where did the death occur?
- Where was the deceased last seen?
- Where did the injury/ies occur?
- Where were the witnesses during the incident?

Why?

- Why was the deceased at this location?
- Why was a crime committed?
- Why was this type of weapon used?
- Why did this death occur at this time?
- Why was the deceased found at this time?

The more detail that can be obtained about what happened, the easier it is to determine what resources are required in examining the scene and the significance which is to be placed on certain aspects of the evidence.

Scene Security

An initial assessment of the crime scene will be made by the first officers attending the scene. The scene will be secured by them to an extent based on the information available at the time. The crime scene manager, who will normally be a senior member of the crime scene staff, must attend the scene at the earliest possible opportunity to take charge of the management of the crime scene. He or she will usually be accompanied by a crime scene investigator or a team of crime scene investigators who will undertake the crime scene examination. The size of the crime scene/s will dictate the amount of resources allocated to the particular incident. It is imperative that the crime scene manager has the authority to allocate the amount of resources required.

Once the crime scene is handed over to the crime scene manager, a reassessment of the scene security should be made to ensure that it is adequate. There should be a formal protocol for the handing over of a crime scene. This ensures control and the maintenance of the scene's chain of custody.

It is an essential element of any prosecution where forensic evidence is involved, to prove the security of the scene and that it was maintained throughout the subsequent examination/investigation. Therefore the objectives of securing the crime scene are:

- To prevent evidence being destroyed or contaminated.
- To ensure security of information; generally information is only released to the media by a media liaison officer or the senior investigating officer.

- To ensure chain of custody of the scene is maintained as is necessary with any item of potential evidence.
- To remove from the scene all unnecessary persons including police officers and the media. It must be remembered that the more people present, the greater the potential for contamination and destruction of evidence. Large numbers of persons present will also inhibit the proper processing of a crime scene.
- To ensure that all evidence has been recorded and recovered. This may include securing the scene until the results of the postmortem or scientific analysis are at hand.

There are a variety of methods for securing the crime scene, for example:

- posting guards;
- rope or printed tape cordons;
- the strategic placing of vehicles;
- the use of markers, flags, signs;
- locking rooms or areas within buildings or using the external walls of a building as the barrier;
- establishing safe walk areas (common approach path) with tape or purpose-built raised stepping plates.

Occupational Health and Safety

The well-being of the crime scene investigator/s is the primary responsibility of the crime scene manager. He or she must be aware of fatigue and well-being of the investigators. Appropriate protective clothing and equipment should be made available. Breaks should be organized for the forensic investigators and refreshments should be on hand during those breaks. Scene guards should also be part of the crime scene operation, regardless of the area they originate from. There should be an area designated where food and drink can be taken, equipment can be stored, and rubbish can be accumulated.

All personnel on site should be briefed regarding:

- safety hazards;
- smoking and eating;
- the location of critical areas;
- the use of telephones and toilets.

Systematic Collection of Potential Evidence

After the general survey of the crime scene, the sequence in which evidence is to be collected and areas searched should be apparent. Priority should be given to:

- any items that are in danger of being destroyed by wind, rain, vehicles, animals, tides, and human movement;
- the collection of any evidence that will enable access to a deceased or any critical area of the crime scene, such as along entry and exit paths;
- those critical areas of the crime scene that may render most evidence or, once processed, enable the removal of a body, or the remainder of the examination to begin;

- any area that may give a quick indication as to the identity of the offender/s;
- any areas that, when processed, will permit the release of scene guards and other resources;
- a general examination of the remainder of the crime scene for potential evidence.

Systematic and Sequential Approach to the Search and Recovery of Potential Evidence

In establishing the manner and sequence of collecting potential evidence, consideration must be given to both, the possible destruction of evidence and to the approach which will yield the best result in terms of useful information. Consultation with other specialists, such as forensic scientists and forensic pathologists, as to the sequence and method of collection may be necessary to ensure the best result; however, this may not always be possible at the scene.

Some examples of collection procedures are as follows:

- Macroscopic evidence should be collected from an area before it is powdered for fingerprints.
- Bloodstains and forensic evidence should be collected from an area before searching for fingerprints.
- Sweepings from the floor around a safe need to be collected before the magna brush is used.
- Polished floors need to be examined first with oblique lighting to locate latent shoemarks/footprints.
- Visible fibers, hairs, and other trace material should be collected from an area before applying general collection techniques, such as tapelifts, sweeping, and vacuuming.
- Tapelift areas of interest before removing deceased persons, collecting sheets and blankets.

In searching critical areas, a search conducted in a clockwise or anticlockwise direction from a fixed point, or conducting a line strip search, makes for a systematic examination. A systematic approach reduces fatigue and ensures a more comprehensive search by minimizing the chance of missing potentially valuable evidentiary material.

Larger objects should be examined before smaller objects and all items should be packaged and labeled at the time of collection.

Examination Records

In order to conduct a thorough, systematic crime scene investigation a proforma should be developed for each activity. These will not be enlarged on here as each jurisdiction will have its own subtle differences, but a list of subject headings for each category of examination is given below. These should be preprepared checksheets that will provide the examiner with comprehensive notes taken during the examination; these proforma records should be available for:

- crime scene log – activities undertaken at the scene, including movements in and out of the scene;
- formal handover of the crime scene;

- list of environmental conditions at the crime scene;
- list of activities and observations at the crime scene;
- exhibit list;
- rough sketch of the crime scene;
- photographs taken at the scene;
- list of specialists attending and times they were involved in the examination.

Ongoing Case Management

Once the scene work is completed, the emphasis changes to the coordination of further examinations and the communication and flow of information of the results from forensic examinations to investigators, and from investigators to forensic examiners. If it is not practical for the crime scene coordinator to chair further case management meetings, another senior crime scene investigator may be nominated to maintain that contact and coordination of the ongoing case management.

Summary

Management of major or minor crime is a matter of seizing control of the crime scene and then the coordination of resource management, along with a systematic approach to processing the scene.

Major crime scenes vary in size and complexity. Some may require many crime scene investigators; others which are uncomplicated may require only one or two crime scene investigators.

Overall, scene management and the maintenance of a two-way communication flow are the two essential ingredients to successful scene management. Regular case management meetings must be held to keep all stakeholders abreast of the latest available information. These must be recorded in the case notes.

Packaging

J Horswell, Approved Forensics Sendirian Berhad, Selangor, Malaysia

© 2013 Elsevier Ltd. All rights reserved.

Background

The ideal method of collecting and subsequent packaging of items for transport to the forensic science laboratory will vary considerably, depending on the nature of the item concerned. Likewise, the material from which a package is fabricated will also vary considerably.

Paper as a Packaging Medium

Generally, the use of paper in the form of bags of various sizes is recommended. Paper bags are fabricated in various sizes and should be readily available. If using envelopes, A4 white bond paper should be employed in the first instance for smaller items such as hairs, fibers, glass, or paint. Place the item onto a previously folded piece of paper, a bindle, or what is referred to as a 'pharmacist's fold,' and then place this into an envelope or plastic zipper bag. This will prevent the loss of items from envelope corners or through the zipper of a plastic bag, and the use of folded paper will simplify the subsequent examination under a low-powered microscope.

The placement of clothing and biological material in paper allows the item to breathe; placement in a plastic bag, on the other hand, may result in bacterial action and encourage the growth of mold. All items should be air dried prior to packaging in paper.

Extensively blood-stained or semen-stained items recovered from crime scenes should be first placed into paper and then protected by a plastic bag with the top left open to allow it to breathe; however, the item must be removed from the packaging material on arrival at the forensic science laboratory and thoroughly air dried.

Items wet with volatile substances should be placed in nylon bags or new, clean, paint cans. Normal polyethylene bags are not suitable for the retention of volatiles.

Infested Material

In some instances, material recovered from crime scenes or mortuaries, which is to be returned to the forensic science laboratory or to be stored as property for long term, may be infested with pests, such as fleas, lice, maggots, or coffin beetles. Care must be taken when examining this material by wearing protective clothing, which includes overalls/laboratory coats, face mask, gloves, and protective eye wear. If possible, always use a large open search bench.

If insect infestation is present within the item, there are at least two methods available for killing them:

- Place the material and container in a large plastic bag and seal it. Place the bag into a deep freeze for approximately 3 h or until the insects are dead.

- Add a few drops of ethyl formate to the plastic bag containing the item and its container. Seal the bag and leave for approximately 1 h or until the insects are dead.

Where blood or semen stains are present, samples from stains must be collected prior to freezing. Consideration should also be given to entomological aspects of the case: both live and dead insect specimens may be required for examination.

Collection of Items

It is better to collect excess material than to have an examination fail because there is insufficient material for examination and/or analysis. Where difficulty may be encountered in collecting minute traces of substances, specialist collection techniques should be employed. If, however, traces of evidence are on small items and there is a chance of loss, the traces subsample should be recovered and placed into a separate package; if circumstances do not permit this, the entire item should be packaged and secured as soon as possible. If the trace is a stain, then the stain should remain on the item for assessment and examination in the forensic science laboratory. This is particularly relevant where the item as a whole is vitally relevant, for example, a blood-stained knife.

In many cases involving stained material, for example, fire debris, it is necessary to submit unstained material for analysis to determine if the material itself interferes with the analytical procedures.

In any comparison of the constituents of two substances, sufficient reference sample material should be provided. For example, if dust on clothing is suspected of being ballast from a particular money safe, a sufficient amount should be collected from the money safe itself, packaged, and submitted together with the items of clothing in order that a satisfactory comparison may be performed. The reference sample should be representative of the source from which the test sample originated. For example, it is useless attempting to compare a body hair found at the crime scene with a head hair from the suspect; like can only be compared with like. Similarly, the comparison of soil from a shoe with soil from the crime scene may be unsuccessful if the sources of the two samples are separated by only a few meters.

Labeling

- The purpose of a label is twofold: to identify the nature and source of the item and to establish a chain of custody.

Ideally, a label should have the following information recorded on it:

- Nature of contents
- Source (where found or from whom recovered)
- Date and time

- Signature and printed name of the collector (or person initiating the chain of custody)
- Sequential collection number
- Unique case identifying number

Additionally, room should be available on the label to record the movement of the item (from hand to hand – person's name and signature, date, and time).

The label should be completed at the time of collection or receipt of the item. If an item is collected from a person, use that person's name, for example, 'Trousers from John Smith.' Do not mark the item with the word 'Suspect' as this wording on exhibit labels can lead and has led to the item being excluded from being tendered as an exhibit in a trial. Some courts are of the view that to mark items in this way is 'unnecessary' and 'objectionable' because whenever such an item is mentioned in evidence during the trial, the jury are being told that the accused has been a 'suspect.' This perhaps gives the impression that she/he was a suspect early in the investigation as well as indicating that the investigating officer and/or his delegate/s may have a fixed view or preconceived ideas regarding the status of the person answering the charges, which may be a view not held by all on the investigating team. The court may also wrongly hold the view that there may be more to know about the accused, which could be prejudicial, particularly in jurisdictions that still have the jury trial system. Obviously, the words 'offender' and/or 'perpetrator' should never be used as this is a presumption of guilt.

The sequential number used should relate to the collectors item list and could be JH1, JH2, JH3, and so on or items 1, 2, 3, and so on. When making a subsequent examination of the items collected, any material removed should be given a number that relates to the original item. For example, a pair of trousers is marked JH1 and hair is recovered from the trousers; this item should be marked JH1.1. Alternatively, if the trousers are number 31 then the hair would be 31.1; if DNA is extracted from the hair then those derivatives would be 31.1.1, 31.1.2, and so on. In this way, each subsample can be easily traced back to the original source item.

If the item is something substantial, for example, a knife or clothing, then the item itself should be marked as well as the container. It may be appropriate to tie a label with a piece of string to the item. If this is done then there can be no doubt about later identifying the item in the witness box should it become separated from its container.

When using plastic pots or vials, ensure that there is a corresponding mark on both the lid and the container to avoid any mixing up of containers. The sequential number and unique case identifying number are normally used for this purpose.

Collection

The proper collection of items and trace material is essential in obtaining the greatest evidential value from an examination. Special clothing should be worn during all scene and laboratory examinations. Scene suites, white cotton overalls, or laboratory coats should always be worn as white cotton has the least evidential value as a fiber and is, therefore, suitable in

preventing contamination of crime scenes or clothing with fibers from the examiner's clothing. Disposable protective clothing is preferable, as it protects the wearer as well as prevents contamination through reuse. There is also an occupational health and safety dimension to the use of appropriate clothing.

Collection Case

Collection cases must be kept clean, with equipment stored in an orderly manner. The principal collection items and their uses are listed in [Table 1](#).

Collection Techniques

A variety of techniques have been developed for the collection of trace material and other potential evidential material. Each technique is designed to prevent damage to, and contamination of, the material. The main collection techniques can be described as

- Handpicking
- Tape lifting
- Swabbing
- Sweeping
- Vacuuming

Handpicking

Whenever examining the crime scene, garments, bodies, or other articles, the initial emphasis should be directed toward the collection of gross and macroscopic items that can be recovered by hand or by the use of tweezers. Items large enough to see with the naked eye should be collected by handpicking. Material such as hairs, large paint and glass

Table 1 Principal items of collection equipment and their uses

<i>Item</i>	<i>Collection use</i>
Scalpel	Paint smears, visible fibers, vegetation, and dried blood
Probe	Paint, fibers, residues, oils, greases, manipulation of microscopic particles
Brush	Trace particles: paint, metals, vegetation, glass
Swab (dry)	Small particles, which will be caught in the coarse fibers of the swab
Paint brush	Sweeping localized and constricted areas
Spatula	Soil samples, whole- or partly-congealed blood, mixing casting compound
Tweezers (metal)	Trace material, such as fibers, hair, and vegetation
Tweezers (plastic)	Items that may be damaged if metal tweezers are used; recovery of projectiles and fragments during postmortem examinations and for use when recovering blood stains using small pieces of moistened cotton. Each pair of tweezers are inexpensive; therefore, they can be destroyed after each use
Cotton	Linen moistened with distilled water for the recovery of dried blood stains
Magnet	Recovery of particles of iron and steel after covering the magnet with plastic

fragments, and pieces of vegetation should be collected before the application of other collection techniques, such as tapelifting, sweeping, and vacuuming.

Handpicking has the advantage of establishing the position of the material on the item and requires no further time in searching, whereas tapelifts, sweepings, and vacuuming have to be further searched to isolate small particulate matter of interest.

When collecting items by hand, disposable gloves should be worn and changed whenever there is chance of contamination between items or locations. Various types of tweezers are available to cope with small particulate matter and a moistened fine brush will recover paint particles. It is essential that each item of collection equipment is cleaned between individual collections.

Tapelifting

Tapelifting is a reliable method for collecting trace microscopic material from a variety of surfaces, in particular, garments and motor vehicle seats. Transparent adhesive tape no more than 7.5 cm in length is applied to the surface of the object. At the completion of the application, the tape is placed over a clean piece of glass or rigid plastic and then placed into a clean labeled plastic bag. Garments and other larger objects should be examined in segments, for example, the front and rear of a shirt as two discrete areas. The tape should only be used while the adhesive qualities remain.

Too much material should not be placed on one tape. The collection of material in this manner facilitates the examination of trace material using a microscope and, in particular, assists in sorting material of interest from a myriad of other insignificant material. When using adhesive tape from a dispenser, the first 5 cm should be discarded to prevent contamination. The method of tapelifting is used more widely in the forensic science laboratory, although it does have its uses in the field, for example, when processing the interior of automobiles.

Sweeping

This method is particularly useful in collecting material from a variety of areas, including inaccessible sites or those where there is a mass of material. Sweeping is also a useful collection technique for the examination of motor vehicles where large amounts of debris can be present on vehicle floor surfaces or in boots.

It is essential that the brush is clean and that separate brushes are used whenever contamination or cross-transfer is a consideration, for example, examining a scene and a suspect's vehicle. New paint brushes approximately 25 mm wide with nonpainted handles, along with new pans from dustpan and broom sets, should be used on each occasion where sweeping is employed.

Vacuuming

The collection of microscopic material, from garments, motor vehicles, and other large objects, by vacuuming is another means of collecting trace material. However, the circumstances in which it should be employed need to be considered carefully, as the vacuuming collected is difficult to handle, involving the expenditure of a great deal of time in searching them in the laboratory. Vacuuming can be too effective, in that it can lead to the collection of a great deal of 'ancient history.'

This method requires a specialized nozzle for the vacuum cleaner. Nozzles are made from plastic where you can place a filter paper to trap and retain material vacuumed from items. In earlier years, nozzles were custom made from stainless steel and connected to heavy duty vacuum cleaners. **Figure 1** depicts two portable vacuum cleaners that are suitable for crime scene and forensic science laboratory vacuuming.

Material is collected by suction on to a clean filter paper that is placed inside the trap. Traps must be cleaned before use, between vacuuming separate items or particular localized areas on an object, vehicle, or scene. The complete nozzle should be washed in warm soapy water, rinsed with clean water, and dried. Bottle brushes are ideal for cleaning nozzle pipes and the trap itself. When in the field that is away from the ability to clean the nozzle, it must be brushed clean between each use, run without filter paper, and then run a 'blank' with filter paper to ensure that the trap and its nozzle are clean.

A blank/control vacuuming should be run before each sampling run, using a clean filter paper in place inside the trap. This is then removed and bagged separately for later examination. Each sample run must also have a clean piece of filter paper. Once set up and ready for a sample run, the nozzle is applied to the surface, for example, with a garment with a series of strokes. Each area of the garment will be a discrete searching area in its own right, for example, pockets, back, and front of the garment. When not in use, the nozzle/trap should be thoroughly cleaned and stored in a sealed plastic bag.

Figure 1 Two examples of portable vacuum cleaners for trace evidence retrieval. '3M' Trace Evidence Vacuum, 'Sirchie' Trace Evidence Vacuum.

Preservation

Items must be preserved, so that they remain, as far as possible, in their original state and may be produced in court in the condition in which they were found. In some cases, it is not possible to retain the exhibit intact, for example, in analytical procedures, the items may have to be altered or it may be totally consumed in the procedure.

The crime scene investigator should take all necessary steps to protect items collected from the following:

Loss: Small items such as hairs, fibers, and paint flakes may be lost from packages that are not properly sealed. Envelopes on their own are unsuitable for small samples as the particulate matter may be lost through corners of the envelope. Volatile liquids from fire scene may evaporate from the containers that are not airtight and impermeable.

Deterioration or damage: Biological material such as blood or seminal stains may deteriorate rapidly. Valuable shoe impressions and blood stains in outdoor scenes must be protected and/or collected before wind and rain may destroy them.

Contamination: Items that are not properly packaged may become contaminated by the introduction of foreign matter into the packaging.

Tampering: Items should be packaged and sealed securely and should not be left unattended at crime scenes. The crime scene investigator should guard against innocent tampering as well as that intended to destroy potential evidence, for example, a firearm left unattended with a fired cartridge case in the breech may arrive at the forensic science laboratory with several impressions on the firing pin if the firearm is not packaged appropriately and secured.

Sealing Containers

The sealing of containers is necessary to keep items from being lost, contaminated, or tampered with. The container should be sealed with sealing tape and then with evidence tape. The evidence tape should be signed by the crime scene investigator/collector.

Chain of Custody

The chain of custody refers to the documentation of possession of items from their recovery collection through examinations to their tendering in court as potential items of evidence. This allows interested parties to trace who has had custody of the item at a given time, as well as being able to account for where the item has been while it has been in an individual's or organization's custody.

Proximal containers and, if applicable, items should be labeled with a movement record of the container/item, and the case file and/or the exhibit movement log should also record the movement of the item.

Hazard Labeling

It will be necessary to mark containers with appropriate hazard labels. Those that contain items that are stained with body fluids should be marked with a biological hazard label, and those that contain items that have been treated with chemicals to enhance

fingerprints should be marked with a chemical hazard label. This should go some way in encouraging court staff to resist the temptation to open all packages and dispense with containers before the item is tendered as an exhibit in court.

Summary

This article has discussed packaging material and how to deal with infested material, along with the techniques employed and the sequence of collecting items.

Chain of custody has also been discussed, as has the use of appropriate labeling and sealing. Appendix 1 outlines the collection of specific items normally encountered in crime scene investigation, pointing out the most appropriate packaging and collection technique and the significance of each specific item.

Appendix 1 Collection and Packaging

The following is offered as a guide to the collection and packaging of commonly encountered items of physical evidence.

Ammunition

This includes projectiles, live and expended cartridges, shot, and wads.

1. Undamaged material can be wrapped with tissue paper and placed into a rigid plastic container. In the case of distorted projectile fragments, place in a small plastic bag and place each item in separate plastic or cardboard container/s. Never mark ammunition – label the proximal container instead.
2. Wash projectiles and air dry if removed from a deceased person during an autopsy before packaging.

Packaging: Item placed into a plastic bag and then placed into a rigid plastic container. Do not use cotton wool or tissue paper for fragmented and distorted projectiles.

Significance: Determine type of ammunition and its origin.

Bite Marks

On Skin

1. Photograph using a digital camera using Polilight® to provide a variety of wavelengths to obtain best contrast.
2. Wipe area around bite mark with a sterile dry swab or piece of cotton then place in container and label.
3. Cast mark if possible.

Packaging: Place swab and cast in separate small rigid plastic containers.

Significance: In consultation with an odontologist, comparison of the bite mark may be made with any suspect's teeth and possible DNA analysis.

On Perishable Items

1. Photograph in the studio to get the best result.
2. Cast mark.

Packaging: Place cast into rigid plastic container.

Significance: In consultation with an odontologist, comparison of the bite mark may be made with any suspect's teeth and possible DNA analysis.

Suspect

1. Photograph teeth recording all teeth from a variety of positions.
2. Obtain a saliva sample using sterile cotton gauze, air dry, and package.
3. Cast teeth of suspect. Casts are taken and usually remain with the odontologist.

Packaging: Place 2 once air dried into a small rigid plastic container. Place 3 into a small cardboard box.

Significance: 1 and 3 are for use by the consulting odontologist for comparison work with bite marks and suspect's teeth; 2 for DNA analysis.

Blood

On Absorbent Material

1. Cut material, air dry, and package separately.
2. Cut out a control sample.

Packaging: Large blood-stained items should be packaged in paper; small samples that have been dried should be placed in rigid plastic containers or wrapped in A4 paper, folded, and placed in paper envelopes.

Significance: DNA analysis. Comparison with reference samples.

On Nonabsorbent Material

Wet: For large volumes of liquid blood, suck up with a spoon or disposable pipette and package in a small glass container. For smaller stains, rub a piece of cotton through the stain, air dry, and package in a small rigid plastic container.

Dry: For large volumes, use a scalpel blade to scrape dried 'peeling' into a small rigid plastic container. For small volumes, rub a piece of previously moistened (with distilled water) cotton through the stain and transfer the stain onto the cotton. Air dry and package in a rigid plastic container.

Packaging: Plastic and glass phials.

Significance: DNA analysis. Comparison with reference samples.

Whole Blood

1. Obtained by a doctor or nursing staff. Consideration may have to be given to relevant local Acts and Regulations when taking intimate body samples. Three samples are required.
2. One straight without any additional material.
3. One with anticoagulant.
4. One with preservative.

Packaging: One sample is placed in a pink top-seeded small rigid plastic container with EDTA, One sample placed in a

brown top-seeded small rigid plastic container with sodium oxalate; one sample in a plain small rigid plastic container.

Significance: Blood alcohol determination of contents of brown-topped plastic container. DNA analysis with the remainder and then comparison of results with crime scene stains.

Bloodstain Pattern Interpretation

1. Photograph the entire scene using digital photography
2. Take overview photographs of stains at 90° from each stain section
3. Take close-up views including a measuring tape
4. Take blood samples from different types of stain as stains may have a different origin

Packaging: As above.

Significance: Aid in the reconstruction of events and using DNA analysis may assist in identifying the donor of the blood stains.

Cigarette Butts

1. Collect with plastic tweezers, air dry if wet, and package.

Packaging: Place each butt in separate rigid plastic containers or glass phials.

Significance: Identify cigarettes. Is there more than one person smoking? DNA analysis on residue saliva, examine for fingerprints and lipstick.

Clothing

1. Photograph, note, and describe.
2. Remove any obvious trace material and package separately.
3. Remove clothing from suspects over clean white paper, air dry wet clothing, and package separately.

Packaging: Place each item separately in a paper bag.

Significance: Search for any trace material for comparison with any reference material. DNA analysis on different blood stains to identify suspects and proof of contact.

Documents

1. Wearing white cotton gloves, collect with tweezers, and package separately.

Packaging: Place in a prelabeled plastic document sheet or envelope already containing a piece of cardboard.

Significance: Indented writing, obliterations or additions, Signature verification, ink comparison and analysis, photocopier identification, and original/overtyped letters or as material for comparison in handwriting analysis in an attempt to identify the writer.

Fibers

1. Collect fibers with tweezers or submit the whole item containing fibers.
2. Using the tapelifting collection technique, tape the area of interest using clear transparent adhesive tape and place tape, adhesive side down, on a clear plastic sheet.

Packaging: Small plastic phial for loose fibers and plastic bags for plastic sheets.

Significance: Identify possible source. Comparison with other known fibers in fiber transfer issues in crimes of violence.

Fire Debris

1. Collect debris from suspect point or points of fire origin. Collect charcoal or burnt wood as this material absorbs minute traces of ignitable liquid residues.

Packaging: Clean new paint cans, nylon bags, or polyvinylidene chloride (PVDC) bags. When using bags, be careful of sharp debris, which may penetrate the bag.

Significance: Determine the presence or absence and type of ignitable liquid residues.

Firearms Discharge Residue

On Hands

1. Photograph and visible evidence.
2. Photograph using various wavelengths using Polilight®.
3. Collect from the web of the hand using prepared adhesive SEM stubs.
4. Take control samples from other skin area where Firearm Discharge Residue (FDR) has not been deposited.

Packaging: Use a commercially or laboratory-fabricated SEM FDR collection kit.

Significance: Determine if a firearm has been discharged by the person being tested.

On Clothing

1. Photograph visible evidence.
2. Photograph using various wavelengths with Polilight®.
3. Package.

Packaging: Paper bags.

Significance: Determine if a firearm has been discharged by the person who was suspected of wearing the clothing.

Projectile Hole in Clothing

1. Photograph visible evidence, location photograph, close-up photograph with tape measure.
2. Protect the projectile by pinning paper over it.
3. Place cardboard behind area to prevent bending.
4. Do not bend clothing at the projectile hole if it can be avoided.

5. Package
6. During laboratory examinations, photograph using various wavelengths with Polilight®.

Packaging: Paper bags

Significance: Determine distance from target. Analysis of residue at projectile hole may reveal the identity of the projectile and, therefore, the ammunition.

Projectile Hole in Dead Skin

1. Photograph visible evidence, location photograph, close-up photograph with tape measure.
2. Cut beyond the blackened area, surrounding the bullet hole and identify the '12 O'clock position' with a suture.
3. While fresh, conduct laboratory examination on the projectile hole.
4. Photograph visible evidence, location photograph, close-up photograph with tape measure.
5. During laboratory examinations, photograph using various wavelengths with Polilight®.
6. Swab around hole, dry, and place in rigid plastic container for SEM EDX analysis.

Packaging: Rigid plastic container when fresh. After laboratory examination, place in a small glass jar with 10% formalin.

Significance: Firing distance and angle of entry and identification of ammunition by chemical analysis.

Glass

At the scene in general area,

1. Photograph both sides of glass before removing it from the frame.
2. Collect fragile fragments first.
3. Wrap each separately to protect edges.
4. Place fragments in a suitable rigid plastic container or cardboard.
5. Collect all pieces if possible.

Packaging: For small fragments, for analysis, use a rigid plastic phial. For larger pieces (direction of breaking and mechanical fit examinations), use cardboard boxes – self-made or commercially available.

Significance: Small pieces as control or reference samples for refractive index measurements; identification of source by mechanical fit examinations and direction of force by examining hackle marks on edge of broken pieces of window.

On Clothing

1. Collect fragile fragments first.
2. Collect clothing and package separately.

Packaging: Plastic phials, larger plastic containers, and cardboard boxes.

Significance: Identify possible source by physical and/or chemical analysis; identify possible source by mechanical fit; and identify direction of force by examining the glass edges.

Hairs

On Moveable Objects

1. Collect and protect the complete item.
2. If there is a need to collect before moving and packaging the garment, then collect.

On Fixed Objects

1. Using a pair of plastic tweezers, collect hairs and package.

Suspect's Head Hair

In cases where during the offense (e.g., armed robbery and rape), a balaclava or other covering has been worn over the head or in breaking case where the suspect could have been in close proximity to breaking glass then a sample of what may be in the hair should be taken. This is undertaken using a moistened seeded comb. The comb is seeded with white cotton wool, moistened with distilled water, and then the head of the suspect is combed. This must be done quickly after the offense has been committed as any foreign material in the hair maybe lost in time. This is not intimate and may be done with the consent of the suspect or in some jurisdictions, a senior police officer.

In rape cases, a seeded combing should also be done where the suspect has come to notice quickly. Both the head and the pubic hair regions should be combed.

During an intimate medical examination by a medical practitioner (be conversant with local legal requirements).

Control Samples

Head: Pluck 30–40 hairs from various areas.

Pubic: Pluck 20–30 hairs.

Others: Pluck 10–20 hairs.

Packaging: Folded white paper inserted into an envelope or plastic bag.

Significance: Human or animal; determine color, sex, and race of person; identification of areas of the body the hair originated from; was the hair pulled or shed; and mitochondrial DNA to identify the person who shed the hair.

Insects: Flies

There are four stages in the life cycle of flies: eggs, maggots, pupae, and adults (flies). Collect across the life cycle.

1. Collect 60–80 individuals from each position, on, under, and approximately 90–150 cm from the decomposing body.
2. Collect from hidden areas, beneath leaves and floorboards.

Note: Pupae may be found in the form of brown capsules under the body or in the soil under the body.

Packaging: Glass container. Place specimens in 70% V/V ethyl alcohol of 10% formalin in distilled water. Place an equal amount of specimens in a plastic phial and freeze. Place an equal amount of specimens in a plastic container with some flesh.

Significance: Estimation of time of death.

Maggots

Packaging: Glass container. Place specimens in 70% V/V ethyl alcohol of 10% formalin in distilled water. Place an equal amount of specimens in a plastic phial and freeze. Place an equal amount of specimens in a plastic container with some flesh.

Significance: Estimation of time of death.

Submit all to the entomologist urgently for examination and identification.

Paint

On Tools or Vehicles

1. If possible collect the item (tool or vehicle) containing the evidence.
2. Collect paint chips separately.
3. Care should be taken not to fragment paint chips.
4. Take reference samples of each color, ensuring that they are scraped down to the base color.

Packaging: Folded white paper inserted into an envelope or a plastic bag or rigid plastic container.

Significance: Determine possible source: color, model, and type of vehicle. Identify the vehicle when it comes to notice.

On Clothing

1. Collect fragile evidence first.
2. Collect clothing and package individually.

Packaging: Folded paper inserted into an envelope or plastic bag followed by its insertion into a rigid plastic container.

Significance: Determine possible source: color, model, and type of vehicle. Identify the vehicle when it comes to notice.

Postmortem Samples

Alcohol

1. Obtain 10 ml clean arterial blood.
2. Obtain 10 ml bladder urine.
3. Obtain 10 ml vitreous humor.

Packaging: Plastic tube seeded with a preservative (oxalate or fluoride).

Significance: Indicates state of intoxication at the time of death.

Blood for DNA and/or Serology

1. Obtain 10 ml of clean arterial blood for each phial.
2. Place one 10 ml lot in a plain plastic phial.
3. Please a second 10 ml lot in a seeded plastic tube containing EDTA.

Packaging: Plain phials and EDTA seeded phials.

Significance: Reference sample for DNA analysis and any other serology requirements for comparison with scene and other unknown stains on suspect or in those found in the suspect's environment.

Drugs

1. Obtain 10 ml clean arterial blood.
2. Obtain 10 ml bladder urine.

Packaging: Plain glass phials without anticoagulant or preservative.

Significance: Indicates if the decedent was under the influence of drugs at the time of death, is a chronic drug user, and met their death through drug overuse.

Toxicology

1. Obtain 10 ml clean arterial blood.
2. Obtain a 100 g portion of liver.
3. Obtain all the stomach contents.
4. Obtain 10 ml vitreous humor.

Packaging: Glass containers of various sizes.

Significance: Identify the presence of any poison present in the body of the deceased.

Diatoms

1. Obtain a portion of the femur bone.

Packaging: Glass container containing absolute alcohol.

Significance: To establish location of suspected drowning, in salt water or fresh water.

Safe Insulation and Safe Surface Paint**From Suspect's Clothing and/or Environment**

1. Collect clothing and package separately.
2. Tapelift and/or vacuum items from suspect's environment.

Packaging: Paper bags for clothing. Plastic bags for vacuum residues and tapelift plastic sheets.

Significance: Comparison of any safe ballast and/or paint found on clothing or in the suspect's environment with a reference sample of safe insulation.

From Safe

1. Collect reference samples of paint and safe insulation from the safe at the burglary site.

Packaging: Small rigid plastic container for safe material and small plastic bags for paint.

Significance: For comparison with any trace material found on the suspect or in his/her environment and, therefore, linking the suspect with the scene.

Saliva

Collect saliva, ensuring that it is saliva and not mucus, on clean white gauze or using a DNA database collection kit.

Air dry and package.

Packaging: Rigid plastic container or DNA database collection kit (jurisdictional specific).

Significance: DNA analysis.

Seminal Stains

Photograph stains for location and distribution.

Photograph using various wavelengths using Polilight®.

Collect items exhibiting stains wearing gloves.

Air dry and package.

Packaging: Paper bags.

Significance: Identification of donor by DNA analysis.

Soil from Scene and Suspect's Clothing and/or Environment

Collect sample from suspect vehicle or footwear.

Collect clothing from suspect.

Collect several 50 g samples from the scene and surrounding area as reference samples.

Packaging: Rigid plastic containers for the soil samples and paper bags for the clothing.

Significance: Geographical origin of samples and a possible link between suspect and scene.

Tools

Photograph where located.

Protect working ends.

Packaging: Plastic bags.

Significance: Location of paint on cutting edge that may match paint at the scene and to link the tool to a particular toolmark.

Toolmark(s)

Photograph (overview, midrange, and close-up with scale).

Make a cast.

Take paint sample if the area is painted.

Recover complete item for further examination if possible.

Packaging: Rigid plastic container or plastic bag. Plain white paper in envelope for paint sample/s.

Significance: Link toolmark to a particular tool.

Vegetation

Photograph various types of vegetation.

Collect samples consisting of complete plants and roots.

Packaging: Paper bags with cardboard stiffening to prevent damage to items.

Significance: Identify species and growth patterns and compare with trace material found on suspect or in his/her environment.

Wires

Photograph site and location of wire.

Protect ends of wire.

Label ends cut on site.

Packaging: Plastic bags.

Significance: Identify tool type and compare with tools submitted for examination for a possible identification of the tool.

Notes

Potential evidence should be recovered and submitted to the forensic science laboratory as soon as possible, and the examination of individual items at the scene should be kept to minimum. *Do not do at the scene what can be done in the laboratory!*

The above are *general* guidelines. Different jurisdictions may advocate some variation on these procedures based on their own SOPs within their relevant quality systems and also in accordance local legislation.

Forensic evidence, which typically begins as a trace, defined as a vestige of a past action or presence, is generally fragile and can be composed of a variety of materials. Evidence is best understood as a specimen instead of as a sample, as the materials that become evidence can hardly be seen as a random representative sample from a so-called population limited to the crime under study. The value of evidence as proof at trial depends on a complex set of inferences, one of which is admissibility. Admissibility requires two things: the trace should be legally accepted as evidence and the evidence should be analytically reliable. Both these things depend greatly on proper preservation of the evidence.

Preservation: A Time Frame Process

Preservation addresses the need to limit or, when possible, eliminate potential alteration, decay, or destruction of evidence. Hence, it covers two domains: crime scene management and evidence management. Proper crime scene management requires securement, protection, and documentation of the scene, and proper evidence management requires adoption of correct sampling and storing processes. Engaging in both these activities will provide the conditions necessary to protect evidence, as well as documentation of the preservation of the evidence to both the analytical and judicial chains of custody. This, in turn, will help prove the evidence's admissibility in court.

This article focuses primarily on how the crime scene environment can endanger crime scene management in the first few minutes after the crime has been committed, how to document the scene, and how to identify, and thus provide counter measures to, conditions that may jeopardize the collected evidence. Taking chronological notes (preparing crime scene and evidence logs) is a safe activity throughout the process. This critical task could be accomplished by a dedicated officer, whose activity could be supplemented by a voice recorder used to register all the crime scene examiners' remarks. Written records should be produced immediately after the end of the crime scene management.

Preservation of the Crime Scene

Locard said that as time elapses, truth evades us. Indeed, as soon as a crime is committed, the crime scene is already modified through the action of the perpetrator, the reaction of the victim, the legitimate intervention of a number of persons (such as witnesses, SWAT officers, medical personnel, patrol officers, and detectives), or natural conditions (such as weather conditions, rain, snow, wind, heat, and cold; and the effects of time, temperature loss, evaporation, microtrace release, etc.).

Recording the scene with film and video on arrival, registering any person who enters or exits the scene, and making

notes of first responders' observations could build a foundation of relevant data that can be used to make sense of traces discovered later, or of traces that are modified. This record may also provide relevant information for the case at hand. For instance, noticing the colors and smell of flames in the case of an arson attack can provide relevant information to investigators and crime scene examiners regarding evidence preservation inside the crime scene.

As traces and evidence are fragile and subject to alteration and destruction, patrol officers should use the above-mentioned procedures to immediately 'cast a protective net on,' or 'freeze,' the immediate scene of the crime. This can be later reassessed by the crime scene examiner. Access to this area should be forbidden, and any person (or cars) on site or around should be identified, including SWAT and rescue team members. As this task is generally performed by patrol officers, the crime scene examiner should verify that it has been completed correctly.

On arrival at the scene, the crime scene examiner should identify himself or herself to all persons on the scene and create a personnel log to record their identifying information. This will allow investigators to obtain relevant information – such as shoeprints, fingerprints, and DNA swabs – from the policemen, firemen, witnesses, etc. who were present at the crime scene. During evidence search and collection, this personnel log will allow the immediate exclusion of traces made by legitimate personnel (such as the bloody imprint of a paramedic's shoe). These personnel logs should contain the names of patrol officers, first responders, firemen, paramedics, the coroner, detectives, the attorney in charge, witnesses – anyone who was in the crime scene before or during its processing. Obtaining DNA swabs, fingerprints, shoeprints, or other comparison materials from these persons could be done later, although photographs of these persons should be taken at the crime scene to create a record of the clothing or shoes they were wearing at the scene.

Crime scene examiners should consult first responders, who can generally provide an understanding of the nature of the site (public, private, commercial; type of activity; size; access points; etc.), to better assess the dimension of the crime scene. This knowledge is necessary to determine the dimension of the area to be preserved. If the crime scene examiner finds that too much or too little area has been protected by the patrol officers, he or she must make immediate corrections to enlarge or decrease the dimensions of the crime scene. Speaking to first responders will also allow crime scene officers to better understand the actions taken by the first responders (the rooms they visited, the objects they touched, and what medical assistance was rendered, etc.), so that they may better appraise the relevant areas and search more efficiently for evidence. As far as possible, pathways used by first responders should be identified and new pathways created, if necessary, to avoid further contamination of the scene. Barrier

tapes or barricades should be positioned to denote these pathways and protect the scene.

Once this primary area of interest has been identified and before its management commences, roads and tracks leading to it should be secured to determine the second area of interest, where partial 'freezes' and evidence searches need to be conducted in the same way. As the scene of crime grows, additional officers may be required to secure the perimeter of each of the separate areas that are beyond the scene. Once these additional areas of the crime scene have been identified, all persons – including onlookers, patrol officers, and first responders – should be removed from those areas. The only persons on the crime scene should now be the few crime scene examiners who are authorized to work on the crime scene, and they should be wearing full protective suits.

Preservation of Evidence

Temporary evidence – such as shoe prints in snow, blood on concrete on a sunny day, impressions in mud in the rain, or even the temperature of water in which a cadaver lies – should be secured before any other evidence is collected or preserved. Securing this evidence may be done by any available means, including but not limited to covering and protecting the site, taking photographs or notes, or measuring the temperature. Although the patrol officers who arrive at the scene often conduct these tasks, it is the responsibility of the crime scene examiner to ensure that all evidence has been properly secured. The crime scene personnel can then begin the physical and chemical collection of evidence following known, standardized – if not accredited – processes.

Collection of evidence at the crime scene should anticipate the need for the preservation of evidence through the use of procedures reducing its alteration. These include visualization with the naked eye, use of a forensic light source, and, occasionally, chemical or physical processing; all these methods should be documented with photographs taken at each stage of the process as well as written accounts of the procedure. Appropriate packaging should be used to prevent damage to the evidence, be it the item itself or traces on the item (such as to-be-developed fingermarks and biological materials). Evidence collection procedures should also be designed to protect the health and safety of the examiner and experts, who may come across hazardous material, including contaminated material and sharps, while processing the crime scene.

To ensure that the proper packing materials are available at the crime scene, the crime scene examiner should assess beforehand not only the items that may need to be analyzed but also the environment that the packaged evidence will be in. Biological evidence (such as blood, semen, DNA, and plant materials) should be allowed to breathe by being stored in packaging that will inhibit putrefaction. These materials should not be stored in packing that might, on the article's movement, wipe off latent traces. Paper envelopes are an excellent container for storage of biological evidence; brown paper bags are better for wet – let them dry, if possible – and soiled clothes. Chemically active products (such as illicit drugs or accelerants) should be stored in airtight containers, such as nylon 6 × 6 bags or hermetic paint cans.

When collecting evidence from cadavers, tapings from exposed skin and clothing can be done with low-impact fingerprint tape, or even Scotch tape, to secure traces before moving the body. Each tape lift is then pressed down upon a clear, appropriately labeled acetate sheet. Cotton swabs moistened with distilled water should be gently passed over any visible stain or bruise on the body. Hands and feet should be sealed in paper bags.

Further evidence collection can be undertaken after body removal, such as pupae or maggot sampling. Half of them will be dipped in a 50% alcoholic solution, the other half packed in a holey box with a few nutrients, and all of it sent immediately to the entomological lab.

Evidence should also be transported in a manner that secures it. Biological or putrescent evidence should be moved in a temperature-controlled (4 °C) container or vehicle. Underwater evidence is best transported in a container filled with the water in which it was found in order to avoid further destruction (such as physical dismantling) or rusting in the outside air.

Judicial requirements for admissibility of evidence can be satisfied by sealing evidence containers with tamper-evident tape and identifying the person who packed it (with the packer's signature, initials, or right thumb fingerprint on the tape).

Threats to Evidence

An additional approach to preserving evidence is to analyze the risks to the evidence from its detection to its final storage – such as physical damage, deterioration, contamination, infection, decomposition, loss, and tampering – then propose solutions to preserve it.

Physical Damage

Physical damage is mainly due to human mishandling and can be easily countered with the following measures:

- Clearly indicating both the pathway to be used to enter and move within the crime scene and the locations of evidence with flags, marks, protective covers, etc. Evidence locations should be marked as soon as the evidence is discovered.
- Protecting any detected trace and stain, particularly if such traces are situated outdoors. Wind, rain, and sometimes sun can damage trace integrity.
- Transporting evidence in a way that prevents breaking and avoids the effects of friction. This can be done by adapting the container to the shape of the item and fixing the item (e.g., with plastic binders) to avoid movement.

Deterioration

Biological materials are very fragile in a hot, wet atmosphere. Chemical materials can also lose some of their properties under these conditions and may also pollute the environment if the seal on their packaging is not airtight. Hastening the collection and submission process is helpful when securing these kinds of traces.

A questioned document or comparison document should never be marked, defaced, or altered. Documents should never be folded, except along their original folds. Documents should not be exposed to sticky materials.

Underwater evidence should be submitted to the laboratory immersed in the water in which it was found. The container in which the water and evidence are shipped should be sealed and sent to the laboratory, where stabilization processes (such as barometric depression, osmosis equilibrium) will be carried out before the evidence is retrieved.

Contamination

Contamination of evidence begins immediately after its deposit. Crime scene examiners reduce the risk of contaminating evidence while collecting it by following protective measures on the crime scene, such as wearing white one use only coats and other protective equipment such as gloves, masks, and goggles. The more latent, microscopic, and invisible the trace, the greater the risk of contamination. The more sensitive the analysis to come – that is, the smaller the trace input – the greater the care and precautions that must be taken. Interpretation of the evidence should take contamination into account.

Unfortunately, the proper collection, packaging, and sealing of evidence cannot completely prevent contamination: properly handled evidence can be contaminated by improperly handled evidence stored on nearby shelves at the evidence depository or laboratory. Hence, the log officer should also assess the vicinity where the evidence and comparison materials under his or her responsibility will be stored, plan different vehicles to transport evidence and any suspected person, and take measures to prevent a suspect from polluting the crime scene (or polluting himself or herself with diffused traces of the crime scene). This can be done by requiring identified suspects to wear the white protective coats worn by crime scene examiners. This should be done as soon as the suspect is identified. Should there be a need for a suspect to enter the crime scene, he or she must wear the protective clothing worn by the crime scene examiners.

Infection

Biological materials collected from the crime scene can be infected by insects, fungi, parasites, etc. Crime scene examiners should take measures to protect themselves when handling these pieces of evidence (such as wearing protective clothing) and to limit the damage that could be caused by these infectious agents. Materials used to collect biological exhibits should be washed once a month with bleach.

Apart from the sampling for entomological purpose (see *supra*), insects can be killed after the evidence has been collected through two techniques: either through a deep freeze of the material or by placing several drops of ethyl formate inside a sealed, airtight container with the material until all the insects have died. Use of the freezing technique would require prior collections of biological stains (blood, semen, saliva, etc.). Removing other infestations requires specialized knowledge. Fully infested clothing may need to be examined as quickly as possible (without ending the infestation) and then discarded.

Decomposition

Biological material can decompose in heat. This process is hastened in wet conditions, as bacterial action supports the growth of mold, and when biological materials are stored in plastic containers. Hence, such evidence should be air-dried before being packaged, preferably in paper wraps or envelopes.

Refrigeration at 4 °C (but not freezing) is required for the preservation of biological evidence. In France, –18 °C freezers are used for long-term preservation of unidentified stains and comparison swabs of jailed suspects.

Charred documents should be protected from decomposition by placing them on top of loose cotton in a dedicated cardboard container. Care should be taken during their transportation.

Loss

The small size of many pieces of evidence must be taken into account when choosing their containers. Small items – such as hairs, fibers, paint chips, soils, pollen, and pupae – can be easily lost through the corners of envelopes, which typically are not sealed. Similarly, vapors can leak out of nonairtight containers.

Tampering

As soon as evidence is collected, it is the responsibility of the crime scene officer to safeguard its integrity against unintentional or purposeful tampering. Until the evidence is sealed in appropriate containers, items of evidence should be clearly marked and not left unattended. An officer can be assigned to guard the evidence at the scene of the crime if many days will be needed to manage it.

Once collected and sealed, evidence can generally be examined by experts working on behalf of both the prosecution and defense throughout the investigation and trial. Such counter-expertise is possible because forensic analyses are generally nondestructive. Destruction of evidence, or modification of its integrity, should be noted, and the appropriate judicial authorities should be notified.

Only two techniques can preserve evidence during transportation from the crime scene to the laboratory and beyond: packaging and labeling.

Packaging

As noted previously, paper is the primary method used to package solid and physical evidence, including dried stain swabs, single traces, powders, macroscopic objects (such as firearms and tools), and inorganic exhibits. Paper containers come in many forms, such as envelopes, bags, and cardboard boxes, and in many sizes. In the case that evidence does not fit into or would be harmed by preexisting containers (such as through friction), crime scene examiners may be required to fashion relevant containers out of available paper materials.

All supports that contain traces (marks, stains, etc.) should be specifically protected, for example, by wrapping them in paper. For instance, the barrel of a gun should be covered with

paper and that paper fixed in place with tape or a rubber band to prevent the loss of organic residue (polycyclic aromatic hydrocarbons) in the barrel, which would indicate whether the weapon had been recently used.

Paper containers will allow damp fabrics and biological material to dry and breathe, decreasing the risk of deterioration and decomposition. Air-drying of such evidence is recommended prior to packaging. If the evidence and support are too wet to package in paper and air-drying is impossible prior to leaving the scene, a plastic bag, pot, or bucket can be used temporarily to transport the exhibit to a safe place (such as the laboratory) where it can be dried. Exhibits that release vapors should never be placed in paper containers. In order to preserve the vapors for analysis, these exhibits (which include low-carbonate compounds, such as solvents that are found in paints, explosives, and accelerants,) should be packaged in sealed nylon bags or new paint cans.

A folded piece of paper can be used to collect scraped or tweezed microtraces such as paint chips, fibers, hairs, pieces of glass, and soil. Once the paper is folded in such a way that the collected item cannot escape, the paper should be stored inside a sealed envelope. This manner of collection will make it easier to examine the collected item in the laboratory under a macro- or microscope.

Regardless of the type of container used to collect evidence, the seal on the container must ensure that the evidence cannot be lost, contaminated, or tampered with. Seals may be made of sealing tape and covered by evidence tape to mark the judicial nature of the container. In France, wax seals bearing the police service stamp prevent tampering and clearly mark that the material is under judicial control.

Labeling

Proper labeling of evidence is vital to evidence management and to preserving the chain of custody. The label for each exhibit should be prepared prior to the collection of the trace. The label should include designated space to be used later to track the chain of custody during forensic analysis, when the evidence may be handled by personnel at several law enforcement agencies, storage facilities, and forensic laboratories. The crime scene examiner should also be aware of the judicial requirement attached to such labeling, to avoid prejudicial judgment and possible rejection of evidence at trial. When labeling pots, cans, bottles, and vials, both the lid and the container should be

labeled to prevent inadvertent mixing of caps and containers, which increases the risk of contamination. Relevant information that should be included on each label includes

- the nature and place of discovery of the exhibit;
- the identity of the collector;
- the hazards (if any, such as chemical, biological) posed by the evidence, which can be marked with standardized hazard stickers applied to the containers and lids;
- the date and time of collection;
- the case the evidence relates to; and
- the exhibit's serial number.

The purpose of the serial number is to uniquely identify each piece of evidence. The serial numbers are recorded in the crime scene examiner's log book. For example, items of evidence, such as a jacket and weapon that had been identified as belonging to Frank CRISPINO, may be labeled 'Jacket of FC' and 'Firearm owned by Frank CRISPINO,' with the serial numbers FC1 and FC2. These numbers provide the ability to identify evidence that originated from these supports. For instance, using the example above, question and comparison fibers could be collected and sampled from the jacket, which would be labeled FC1.1 and FC1.2, respectively. In the same manner, a fingerprint found on the weapon would be labeled FC2.1. After securing the fingerprint, a final swab (which would be labeled FC2.1.1) could be done, probably leading to a DNA profile. Hence, the numbers make it apparent that FC2.1.1 was derived from the DNA profile in the fingerprint (FC2.1), which was in turn derived from the firearm (FC2) found in Frank Crispino's possession.

Background

The accurate recording of details of a crime scene, incident scene, or any subsequent examination of potential evidentiary material is important for several reasons. It is important for the crime scene investigator as it will provide the basis for the statement and report that the crime scene investigator must prepare at a later date and it will provide investigators with information of which they may not otherwise have knowledge. It will also assist the court in reconstructing the scene and may provide the most reliable facts regarding potential physical evidence, critical measurements as well as its positioning within the scene. Finally, it may provide the court with best evidence available.

Notes

Experience has demonstrated that crime scene investigators can never make too many notes during a scene investigation and subsequent examination of potential evidentiary material. Notes should always be compiled during the course of the investigation, be it onsite or later when examining potential physical evidence. Notes should not be done later; however, if it is not possible to do so then details should be recorded as soon as possible after the examination/s.

There are obvious and very good reasons for compiling contemporaneous and accurate notes:

- Notes made at the time of an examination are likely to be more reliable and accurate than notes made some time later.
- By making notes as s/he is conducting the examination, the crime scene investigator is less likely to overlook minor details committed to memory.
- An accurate record of times and dates will be maintained. This will avoid discrepancies with the records of other investigators involved in the investigation.
- An accurate record is available for later reference during the investigation and when compiling reports.
- An accurate record is available for later reference during the finalization of the investigation when compiling a witness statement for court.
- When giving evidence in court, the crime scene investigator may be permitted by the court to refresh his or her memory by referring to the notes taken during the investigation and while conducting any specific examination/s.

Obviously, if notes are made during the conduct and at each stage of an investigation and or examination of potential evidentiary material, then there should be no dispute as to their accuracy.

The main aim therefore for writing comprehensive notes is to provide an accurate and comprehensive record of events and observations which will be meaningful months later. For this

reason, it is preferable to write detailed notes at the time rather than attempting to save time by using abbreviations, which, although readily understood at the time of writing, might be insufficient to refresh the crime scene investigator's memory after several months have lapsed.

On arrival at a scene, the following should be noted:

- Day, date, and time of arrival
- Names of persons present at the scene on arrival
- Weather conditions
- Lighting conditions at night
- What has happened – the incident?
- What has taken place – activity at the scene since the primary incident?
- Officer-in-charge of the case
- Scene guard
- Assistance provided at the scene
- Other resources already requested

The sequence of the crime scene investigator's actions following arrival at a scene will vary depending upon the situation with which s/he is faced. If there is no requirement to start a particular examination immediately, it is advantageous to spend some time studying the crime scene, noting all observations. Any movement through the crime scene, noting observations, can only be done if there is no risk of contaminating or damaging possible evidence. A pathway should be identified, which is used as a common approach path into and out of the critical areas of the crime scene.

Photographs

Photographs can provide a detailed record of the condition of a scene, illustrating the items present and their relative locations. For this reason, photographs should be taken before items are moved or interfered with, and should be taken from various angles.

There may be items shown in the photographs which were not mentioned in the written notes taken at the time, and the photographs may help to refresh the crime scene investigator's memory on some aspect of the scene or examination. On the other hand, during court hearings, defense counsel may cross-examine the crime scene investigator about objects shown in the photographs, and if there are no notes made about the issue under examination it may prove embarrassing. It is therefore important not to rely too heavily on photographs alone without the assistance of supporting documented notes.

A general survey, where the scene is inspected before photographs are taken, will help determine what photographs will be required and the sequence in which they are to be taken. As a general rule, the scene should be photographed after the general survey and before further examination/s are conducted, without reconstructing the scene in any way. The crime scene investigator

should be able to demonstrate photographically how the scene was before the start of the scene examination.

It is not the intent of this article to provide a short course on photography; however, the points raised will ensure that there is adequate coverage of the scene by the crime scene investigator.

Before commencing the photographic aspect of the crime scene investigation it must be remembered that photographs should not include items introduced by the crime scene investigator and other investigators. Brief cases, clipboards, photographic equipment bags, crime scene kits, or the photographer's feet should not feature in any of the photographs.

Each crime scene will be different but the following should be considered:

- The photographic record should be comprehensive and should include the general layout of premises or features of an area.
- The photographic record should illustrate the relative positions of room, the state of those rooms, and the position of houses in streets in relation to the crime scene.
- Footprints, tyretracks, and toolmarks should be photographed with a scale before casting. A close-up and positioning photograph should also be taken.
- Photographs should be taken from a number of angles or positions, including those described by witnesses, if known. These may be taken later if not known and are required.
- A series of photographs should be taken from the point of entry to the point of exit.
- Detailed photographs should be taken of potential evidentiary material, such as the body, injuries, weapons, trace material, cartridge case/s, damage, and other relevant items.
- As the scene examination progresses, further photographs should include new potential evidentiary material found, or areas of importance which were previously concealed.

Before taking any photographs, the crime scene investigator must reflect on:

- What am I going to photograph?
- Why should it be photographed?
- What do I want to demonstrate using photography?
- How can I record it as I see it?

Having made these comments, it is necessary to cover all pertinent material. It is wiser to take too many photographs than too few. It must, however, be remembered that it is not necessary to have all the images printed. This should create no problem in court as long as the investigating officer is aware of the situation and it may be necessary in some jurisdictions to advise the defense of their existence. One way to cover this point is to have the investigating officer involved in the selection of the photographs for presentation in the crime scene investigators court statement. This issue will certainly be addressed if the defense obtains a court order to 'produce all documents.' The crime scene investigator should be prepared to defend the selection of photographs in the witness box.

Digital Photography

Digital photography is now being used widely in policing including the capture of images at crime and incident scenes.

It is not my intention to go into this medium in any detail except to say that the increase in memory available for each image has given this media abilities which far surpass silver halide or traditional photography. Crime scene investigators can now:

- See instant results and know they have what they want to record, recorded.
- Use the magnifying component to look at detail in the image.
- Move images between investigators as attachments to email messages.
- Move images instantly over long distances in the course of the investigation.

Images can be easily manipulated but they can easily be checked for alteration if required which now makes this media ideal for use at crime and incident scenes. The crime scene investigator must remember that when giving evidence he should be prepared to state that the picture clearly represents what s/he saw at the time when s/he took the photograph. This should negate interference with the image after all the issue will then become one of credibility of the witness.

Video Recording

It is useful to video the crime scene; a recording may be an invaluable briefing tool for investigators and others to view later, as well as to introduce as potential evidence in court.

The recording of a crime scene by video be undertaken in each serious and major crime. Experience has shown that the video of any crime scene should be taken without sound. The subsequent audiences that view the video should be guided through it by the crime scene investigator or investigating officer, either in person or by means of a 'voice over.'

The video recording of what is called a 'reenactment' should be attempted only after the suspect has been interviewed and the crime scene has been processed, and only after an invitation to participate is accepted by the suspect, with the video being taken with full sound while the suspect is under caution. Such videos have been shown to be a very successful tool in presenting the prosecution case at court. The court will also be able to see if the suspect is under stress or duress at the time of the reenactment video, along with his or her general demeanor and that of the interviewing officer. Experience has shown that powerful evidence can be gained from this recording technique.

The video recording of a crime scene and any subsequent reenactment video should be done under the direct control and guidance of the crime scene investigator or crime scene manager, as it is only these individuals who are aware of the current position regarding the processing, recording, search, and recovery of potential evidentiary material at the crime scene.

Plans

There are two types of plan: a sketch drawn by the crime scene investigator and a scale plan, which can be drawn by an experienced crime scene investigator or a draftsman. These

complement written notes and photographs and are notes recorded of the crime scene examination. They may provide perspective and will provide distances between objects within the scene. Computer programs and photogrammetry are tools that can assist in producing professional scale drawings.

Computer-Aided Design

Computer-aided design (CAD), also known as computer-aided design and drafting (CADD) is the use of computer technology for the process of design and design documentation. Computer-aided drafting describes the process of drafting with a computer. CADD software, or environments, provides the user with input tools for the purpose of streamlining design processes; drafting, documentation, and manufacturing processes. CADD output is often in the form of electronic files for print or machining operations. CADD environments often involve more than just shapes. CAD is used in crime scene drafting producing professional results.

Photogrammetry

Photogrammetry, as its name implies, is a three-dimensional coordinate measuring technique that uses photographs as the fundamental medium for metrology or measurement. The fundamental principle used in photogrammetry is triangulation. By taking photographs from at least two different locations, so-called 'lines of sight' can be developed from each camera to points on the object. These lines of sight, sometimes called rays owing to their optical nature, are mathematically intersected to produce the three-dimensional coordinates of the points of interest.

Triangulation is also the principle used by theodolites for coordinate measurement. Crime scene investigators familiar with these instruments will find many similarities and some differences between photogrammetry and theodolites. Triangulation is also the way the two human eyes work together to gauge distance which is called depth perception.

The choice of equipment to draw crime scenes is one of 'practice' and 'procedure' of crime scene investigators within a given jurisdiction.

I will now, however, go back to the basics for crime scene sketching.

Sketch Plan

A sketch enables the crime scene investigator to show the location of items and their relationship to other items. A sketch only needs to be freehand, it must be neat enough for the crime scene investigator or draughtsman to accurately interpret the data at a later date in order to produce a scale drawing.

There are several basic types of drawing that are commonly encountered in sketching crime scenes. The floor plan view is the most common and is the easiest to complete. It depicts the location of items looking down from above. This should be used for both indoor and outdoor scenes. The exploded view or cross-projection method is similar to the floor plan view and

differs only in that the walls fold out to reveal items of evidence found on or in the walls. Isometric projection of walls as stand-alone drawings may be used to indicate items of evidence, such as bloodstain patterns found on walls at a crime scene, recording extreme violence. Three-dimensional drawings, virtual reality, and animated computer programs are now being used more and more in crime scene investigation.

Coordinate and Triangulation Methods of Measuring Crime Scenes

The following two basic methods are suitable for measuring crime scene:

- *Coordinate method*: This method uses the principles of measuring the distance of an object, such as a body, from two fixed points. One form of the coordinate method involves the use of a baseline, which is drawn between the two known points. The baseline may also be a wall or drawn as a mathematical center of a room, the exact dimensions of which are known. The measurement of a given item is then taken from left to right along the baseline to a point at right angles to the item which is to be plotted.
- *Triangulation method*: The triangulation method requires three measurements:
 - Base
 - Shortest side of the triangle
 - Longest side of the triangle

An established base may be used, for example, the side of a house. Two measurements are then taken, from the corners of that side of the house to the item to be plotted. When a crime scene is in an open area, such as a beach, paddock, or park, the triangulation method is usually employed but it is necessary to establish a base. This can be achieved with the aid of a magnetic compass to determine true north, the taking of coordinates using a Global Positioning System reader, and the placement of a peg in the ground or the use of an electricity pole or something that is fixed and may have a serial number fixed to it.

Procedure for Measuring Crime Scenes

- Accurately determine north with a compass and place it at the top of the plan.
- Determine the crime scene position coordinates using a global positioning system reader.
- Determine what is to be included in the plan and the method of recording it.
- Draw a rough sketch on which the items will be plotted and the measurements recorded.
- Work systematically throughout the scene, recording dimensions, in the case of a room, and the location of important items within it.
- It is ideal that the person responsible for both the sketch plan and the scale drawing be the person who records the measurements on the sketch plan.

- Use the progressive system of measurement where possible; for example, corner of a room to the nearest point of window 0.3–3.5 m to the other side of the window frame.
- In order to locate items within a room or open area, use either the coordinate or triangulation method or a combination of both.
- The position of bodies and important items should be plotted prior to removal or collection; however, the position of 'fixed' objects may be recorded at a subsequent time and date, thus enabling a quicker examination of the scene.
- If objects must be moved prior to plotting then mark their location before moving them, for example, with chalk, felt marking pen, crayon, or spray paint. Remember photographs must be taken before anything is moved.
- Add the crime scene investigator's name, the case, date, time, and location. If anyone assisted, his or her name should also be included on the sketch.

Scale Plan

Scale plans are used to convey accurately the size, shape, and position of important potential evidence and other features of the crime scene. They are a valuable adjunct to scene photographs. Scale plans are also an aid in reviewing a crime scene with investigators.

The use of modern surveying equipment at the scene overcomes many of the problems encountered in preparing crime

scene plans. These tools along with those mentioned above are now being put to good effect by many practitioners.

Computers

The use of computer technology has also advanced and recorded material that was provided to courts in hard copy can now be shown to judges, juries, prosecutors, and defense council simultaneously through linked computers. The paperless office has at long last arrived in the court room!

Summary

The fundamental reason for recording crime scenes is to take a crime scene and reproduce what has occurred for the information of the investigation team and, ultimately, the court.

Glossary

Cordon A defined area around a body recovery site into which access is only granted with permission and which is recorded.

Ossification The name given to the process by which cartilage in a juvenile is replaced by bone during maturation growth.

Spit A thin lens of soil taken over a certain area from a thicker layer of similar soil to enable accurate recovery and interpretation of items within it.

Stratigraphy Layering of soil that has accumulated over time from the oldest layers at the bottom to the youngest at the top.

Introduction

Fundamentally similar techniques are utilized in every problematic human remains recovery. Search and recovery must withstand scrutiny in court, so careful scene examination is vital, helping to determine whether a crime has been committed, by whom, and how. Selection of the correct experts may further determine whether or not an investigation has a satisfactory conclusion. You know what you find but may never know what was missed.

Good communication between forensic specialists and law enforcement officials is vital in problematic body recovery. The responsibilities of law enforcement officials may impact upon specialists, while one specialist's intervention may be contraindicated to another. Determining the recovery strategy ahead of any intervention, followed by good scene control, helps minimize this risk. Each case is assumed suspicious until proven otherwise.

First Officers on the Scene

The first officers protect the scene with inner and outer cordons. Witnesses will be detained separately and notes taken as the scene changes. Senior officers are informed and a crime scene manager (CSM) requested.

Crime Scene Manager

The CSM is responsible for the health and safety and the security of evidence at the scene, using common approach paths (CAPs), cordons, and scene entry (log) books to document everyone entering the scene. They inform the senior investigating officer (SIO), instruct photographic record, and determine personnel and equipment requirements.

Senior Investigating Officer

The SIO directs the police investigation, liaises with media and public prosecutor, informs the pathologist, and invites relevant experts including scene examiners, forensic scientists, and prosecutors to a forensic strategy meeting ahead of the recovery.

The SIO reports to the public prosecutor who ultimately prosecutes the case.

Forensic Scientist

Scientists locate, recover, and interpret various categories of physical evidence; interpret blood spatter, cast tire, and tool marks; and recover fragile trace evidence including blood, hair, semen, accelerants, or firearms discharge residue.

Crime Scene Examiner/Photographer

Either one or two operatives depending on local procedure, scene examiners locate and seize physical evidence, take photographic record at the locus and postmortem, and recover items for fingerprint examination and lift fingerprints.

Production/Exhibit Officer

Exhibit officers seize, package, record, and store evidence to ensure a secure chain of custody and submission to the correct experts for further examination.

Forensic Pathologist/Medical Examiner

The pathologist/medical examiner views and swabs the body at the scene and does a postmortem to establish the cause of death. They may confer with a forensic anthropologist regarding bone trauma.

Forensic Entomologist

Forensic entomologists use the life cycle of invertebrates including flies (eggs, maggots, pupa, and adults) and beetles to refine time of death in problematic cases. Human DNA may also be recovered from larvae/puparia.

Forensic Anthropologist

Forensic anthropologists examine human bones to determine trauma, sex, stature, age at death, ancestry, and health to ascertain identity and cause of death.

Forensic Archeology

A forensic archeologist undertakes body recovery and trace evidence gathering for courts. Working with forensic botanists, they locate clandestine graves; excavate; record and lift the remains; search the area around and below for evidence; and take soil samples to help link tools, weapons, vehicles, clothing, or a suspect to a deposition site.

Forensic Botany

Forensic botanists use vegetation changes to find concealed bodies; date the deposition; explain events at the scene and interpret plant trace evidence to link a perpetrator, tool, vehicle, or weapon to a scene. Some may do pollen analysis (palynology), although palynologists are often geographers.

Police Search Team

Highly trained in an extensive range of search environments including sewers, river beds, cliff tops, or quarries, these officers search large areas rigorously. Their methods may destroy fragile trace evidence so they stop after finding the remains, returning to sweep the area once the scientists are finished and the body recovered.

Scene Processing

Securing the scene and wearing full protective clothing, gloves, and face mask to prevent DNA and other transfer helps minimize cross contamination. Eye protection may also be required.

Search Techniques

Discovery of decomposed human remains can be intelligence led following informant information or during a structured search. Others are discovered accidentally. Protocol demands that informant information is verified and bones confirmed as human before searches begin. Police search advisors then assimilate information regarding landscape boundaries including quarries, rivers, housing, and woodland to define search strategies, identifying hazards that require specialist equipment or personnel.

Standard search methods are adapted to suit the terrain, dividing the total area into smaller, manageable sectors with unique identifier codes. Methods include:

- **Grid:** large grid 'squares' (sectors) are searched methodically, individually, and consecutively. Sectors may be further subdivided. When remains are found, close grid search across the actual deposition spot ensures rigorous, accountable evidence recovery.
- **Line:** a line of personnel walk at arm's length to look for a body, weapon, etc. Closer scale searchers shoulder width apart on hands and knees will find small evidence such as ammunition casings.
- **Zone:** a grid-type method for smaller, irregularly shaped areas.

Methods utilized depend on the terrain, number of searchers and the purpose of the search, whether a missing person, phone, or shotgun casing. A combination of some or all methods may be used. Whenever anything potentially relevant is found, it is photographed, recorded, and either collected or flagged before the search continues.

Dogs

Trained dogs can find evidence, bodies, or trapped live individuals. Training for different functions varies, so dogs taught to find cadavers may not find live victims and vice versa. Dogs can be cross-trained for various searches, such as blood and drugs, arsons or explosives, but are less effective than specifically trained cadaver dogs.

Buried Remains

The time of year, terrain, duration of burial, and exposure to weather will affect what is visible to find. Dismembered body parts may have multiple, small burials rather than one, grave-sized plot. Disturbed vegetation and soil, compaction, differential drying, and random piles of mixed soils are indicators of burial sites that may or may not be seen.

Disturbed Vegetation

Grave digging disturbs overlying vegetation. Recent cases may have upturned roots, broken stems, or wilted stems. A flattened area may be obvious within the undergrowth. Bare soil gradually becomes revegetated, the young shoots highlighting the grave until indistinguishable from the surrounding vegetation.

A body within vegetation becomes better concealed over time. However, a long established burial hidden by tall summer growth may be revealed over winter as a sunken hollow when vegetation dies back. A deep, substantial grave with vegetation carefully removed and replanted may be concealed within weeks, while a shallow, hurried grave may remain obvious for months or years. This is because the decomposing body releases toxic volumes of nutrients that inhibit growth over shallow graves until remains decompose and soil nutrient levels benefit rather than inhibit vegetation. The time for this depends on season, temperature, and invertebrate activity.

Soil Compaction and Disturbance

Soil accumulates naturally in layers (strata) over time. Impoverished glacial subsoils have high clay and gravel content while fertile plough soil is organic and sandy. Glacial events, bedrock weathering, organic accumulation, and human intervention contribute to the 'stratigraphy' (layering) of soils. Once disturbed, natural stratigraphy is changed and may be identifiable.

Graves retain water since the fill is less compacted than surrounding soils, which may assist or hinder vegetation recovery in different environments. The body within means less soil fits back in, leaving a mound that gradually sinks as soil settles into the decomposing body cavity. Conversely, if the grave surface is flattened, leftover soils and stones may be nearby, a depression becoming very noticeable as grave soil collapses into the body cavity. In warm weather, grave margins

may crack since the fill is wetter than the surrounding soil. This is often emphasized by collapse of grave soil into the body cavity.

Infrared Photography

Used in darkness to detect temperature differentials, infrared photography has best application in aircraft-led wide area searches for recent cases. A large maggot biomass that raises the body temperature can boost success rates.

Methane Detection

Methane escaping from a body can indicate a burial, although all decomposing organics produce methane gas and detection rates decline considerably over time, so this technique is only used to investigate small suspicious areas using dogs.

Aerial Photography and Maps

Preexisting and new aerial images can be compared to identify suspicious areas. Photographs are examined in conjunction with maps to exclude nonsuspicious events like pipelines, natural features, or archeology. Aerial photographs also highlight new construction within the period under investigation.

Geophysical Survey

Geophysical survey techniques identify underground anomalies when surface examination is not practicable. Techniques include:

- **Resistivity:** measures speed of electrical current underground between two electrodes, giving a peak with loose, wet soil, including graves and archeological features. Works with agricultural soils but not waterlogged or arid landscapes.
- **Magnetometry:** detects anomalies in the soil's natural magnetic signal caused by infilling the grave with mixed soils with different magnetic signals. Works in wet or dry landscapes but is affected by underground/overhead cables and metal on clothing.
- **Ground-penetrating radar:** a common technique for urban environments, detecting voids to 3 m below concrete or hard standings. Avoids excavating such areas during wider searches.

Construction Equipment

Although a last resort, a backhoe and bulldozer operator guided by an experienced archeologist can remove 5–30 cm of soil at a time to expose disturbance or a grave cut. The potential for damage to the deceased is considerable.

Recovery of Human Remains

Surface Recovery

Inner and outer cordons established across the body deposition site and surrounding area will restrict access and protect evidence. All personnel entering the outer cordon are logged by a designated cordon control officer. A CAP through the inner cordon to

the body that avoids routes likely to be taken by a perpetrator is established, defined with tapes, and searched before use. The site is photographed and a strategy meeting set up with specialists to plan the methodology of recovery. Video images facilitate decision making. A command/control post may be set up at the outer cordon for personnel to gather for briefings.

Photographic record is taken throughout the recovery process. Fragile biological evidence is of paramount importance and must always be first priority, especially if recent, where the body will be sampled in situ. Observed by the biologist, the botanist and archeologist record, clear, and examine overhanging vegetation and debris, recording indicators of duration, trauma, or scavengers. The botanist notes vegetation overlying and growing through the remains to determine the duration of deposition. During and following the body recovery, the entomologist collects invertebrate evidence to corroborate this. A grid is set up across the site, the size reflecting natural boundaries including walls or logs, but with a minimum perimeter of one grid sector surrounding the remains that is free of visible evidence. The size of grid sectors used is situation dependent, but 0.5 or 1 m² are normal. The grid is labeled alphanumerically with markers to give each sector a unique identifier. The grid facilitates accurate, relative spatial recording of items recovered and ensures rigorous search. Spatial patterning of evidence and remains can be reproduced diagrammatically for the court to explain even complicated sequences of events at the scene. Prior to evidence recovery, a metal detector will highlight any hidden weapons, needles, or armament.

Items located are marked with a flag or stake and plotted on a scale drawing of the grid. When reproduced by an illustrator for the court, this sanitizes the image for explanation to a jury, ensuring they focus on the specialist interpretation of evidence without the distraction of distressing images. The grid is photographed to show the distribution of flags, then individual close-up images of items are taken, scales and markers denoting their original grid square and size. Evidence is packaged and recorded by the exhibits/evidence recovery officer. Dry evidence is generally packaged in paper products (paper fold, bag, or box), and wet items within plastic bags. Wet items are dried subsequently in a forensic drying cabinet. Liquids can be recovered in glass or polythene vials. Evidence at fires must be packaged in special acetate bags that will not give false positive results if tested subsequently for accelerants.

The methodology of surface body recovery varies with circumstances. The location of each bone from a single disarticulated skeleton within the grid should be recorded, with bones packaged and then placed together within a body bag. Bones separate from the rest of the body should be wrapped individually but those within clothing may be retained together. Separate body parts may retain other evidence upon them and should be packaged individually with grid locations noted, although they may still be placed within the same body bag. In an intact or almost intact cadaver, the hands, feet, and head are protected by bags before moving. Clothing on a fresh body is carefully removed to prevent semen or leakage from wounds contaminating fabrics and distorting the interpretation of events. This is not generally relevant for decomposed remains and may increase disarticulation.

With the body and superficial evidence removed, the area may be checked again with a metal detector prior to the recovery and search of soil within the gridded area. The archeologist recovers soil down to an undisturbed layer to confirm that nothing was hidden below the body or has sunk into the substrate over time. Soil is recovered per grid sector down to an undisturbed level and either removed for washing and subsequent examination for fibers, hairs, etc. for a recent investigation, or sieved on site for teeth, missing bones, fingernails, projectiles, or small jewelry for skeletonized remains where recovery of fragile biological trace evidence is no longer viable. A sieve of maximum 3–6-mm diameter should be used for sieving of soil on site but finer-gage sieves or 1-mm mesh supported within a sieve are appropriate when washing soil for very small items, in the laboratory or at the locus. The entomologist observes the soil recovery process and collects invertebrates throughout.

Poisons, drugs, or accelerants can be retained in soil beneath the remains, so samples should be collected for analysis. Representative samples of soil within the locus and likely offender access paths are also recovered to enable cross-comparison with sediment found on any footwear, tools, weapons, clothing, or vehicles recovered subsequently, to help link them to the scene. This is crucial since soil from the locus will not remain representative once disturbed by the excavation team.

With the gridded recovery of the main deposition complete, the team moves on to recover evidence or body parts elsewhere. If the skull has detached from the neck bones, it may be some distance from the main decomposition, especially on sloping ground or if scavengers are active. Consequently, the ground between must be searched for additional evidence. Items moved by scavengers may or may not require a grid search, although rigorous recording and packaging remain standard practice. If bones are missing from a body on banking above or on the flood plain of a river, search of the river bed downstream is required. Depending upon the current, heavy long bones may not travel as far as vertebrae or ribs, but some may never be found. Remains settle in river bends or snag in submerged debris, so water searches will require divers and appropriate health and safety guidance.

The total time needed to recover scattered human remains and related evidence, then search for bones missing at post-mortem may be days or weeks, so weather, comfort, and health and safety must be considered accordingly.

Excavation of Buried Remains

Three common methods of excavation are utilized to maximize evidence recovery potential in graves. Gridding the grave helps define locations of soil and evidence recovered during the process. Standard archeological practices including detailed recording, drawing, planning, and photographic record apply in all circumstances. Methods include:

- **Within feature:** grave soil is gradually removed to reveal the remains. Excavating half at a time shows the processes of concealment. Careful excavation up to the grave cut may reveal tool marks on the four grave walls. It is difficult to remove remains from deep graves using this method.

- **Trench:** a trench is dug adjacent to the grave, at least 0.5 m deeper than the body surface. The trench must be longer than the body and wide enough to provide sufficient room to work in to collect evidence and the remains. Three of the four walls of the grave can be defined and the grave infilling processes revealed.
- **Table:** a table is dug by trenching all around the grave cut, approximately 1.25 m wide by 2 m long, extending 0.5 m beyond it, leaving all four grave walls intact and providing sufficient room to work around the body. It provides ease and comfort while working but one wall must be dug through for recovery from deeper graves.

A combination of any or all three methods may provide the optimum evidence recovery potential in problematic circumstances.

Prior to excavation, the body position is estimated, based on visible indicators and extent of the disturbed area. Soil is recovered in layers (spits) of approximate 5–10-cm depth, respecting the overlying grid and any grave soil stratigraphy. Numbering spits makes each layer uniquely identifiable and enables three-dimensional (3D) spatial patterning of evidence. Each spit can be sieved for missing bones and small evidence, the locations of which can be illustrated diagrammatically to help interpret the sequence of events. Coins, jewelry, projectiles, paint, fabrics, ID cards, imported vegetation, SIM cards, and more have been recovered from sieved grave soils.

The hands, feet, and head of an intact body are protected by bags. The easiest way to remove an intact body is to slide it onto plastic over a body bag on a wooden backer board and wrapping before lifting it. This helps prevent disarticulation of decomposing remains. Skeletons should be recovered like a surface recovery. Soil below the body is recovered to an undisturbed layer, checking first for any footwear imprints left by the grave digger(s). Soil below the body should be sieved for additional evidence including bones, projectiles, and teeth.

Forensic Anthropology

The forensic anthropologist reconstructs the skeleton when a decomposed body is recovered, including shattered bones. Identification of pre- and postmortem skeletal trauma in relation to preexisting disease or injury helps determine cause and/or manner of death. Analysis of the skull, pelvis, and long bones confirms gender, height, age range, and possible ethnic origin in addition to trauma and illness. Ribs and vertebrae are also useful sources of data.

Depending on counting methods, the adult human skeleton has 206–211 bones. Juveniles have more since many bones have independent parts in the infant that fuse at different stages during growth and maturation. This facilitates age determination in juveniles. Unfused parts are contained by cartilage that gradually ossifies, enabling bones to increase in length and diameter as the child grows, develops, and matures. Gender and ethnic origin of prepubescent juveniles cannot be determined confidently. Juvenile epiphyses (joint ends) resemble amorphous clay, so soil from a juvenile recovery should be sieved with a forensic anthropologist in attendance. Growth and bone fusion is usually complete by the age of 25, after

which age can only be related to degenerative change, with correspondingly wider estimation parameters.

Teeth and Odontology
